Examples 492 and 496 describe other applications where accuracy was a primary requirement. In the example that follows, a hydrofoil shaft was designed, for economy, in five sections to be semifinish machined, shrink fitted, and welded to very close tolerances, using a small-diameter beam.

Example 483. Electron Beam Welding of 4130 Steel and Monel K-500 Sections of a Hydrofoil Shaft (Fig. 33)

Each of the three drive shafts (Fig. 33) used on a hydrofoil watercraft consisted of five sections, which were shrink fitted and electron beam welded. Four sections were

4130 steel; the fifth was Monel K-500 (see section A-A in Fig. 33). Material and machining economy were the main reasons for sectional construction. Sections were machined from readily available tubing and bar stock. High-integrity welds were required for strength, and permissible distortion was limited to ±0.002 in. for concentricity and straightness before final machining. Each shaft was required to deliver 3600 hp at 5000 rpm, and had to balance within 0.050 ounce-inch before it could be installed.

Prior to the selection of electron beam welding, three alternative welding processes were considered. Distortion would have been excessive with gas tungsten-arc and gas metal-arc welding because of the high heat input from multiple-pass welding. Also, selection of a filler metal that would be suitable for a joint between 4130 steel and Monel K-500 would be difficult. Friction welding, which is normally suited to this type of application, gave no assurance of accurate joint alignment, and the small number of drive shafts to be produced (fewer than 12) did not justify development work on a specialized precision technique for friction welding.

The electron beam welding procedure was closely linked with the shrink-fitting operation, in that each joint was fitted and welded separately. After the first two semi-finish-machined sections (sections 1 and 2) were vapor degreased, the female section was heated to 350 F, the male section remaining at room temperature. These two sections were assembled and were held under hydraulic pressure of 3000 psi for alignment (initial interference was 0.001 to 0.002 in.). After cooling, the assembly was checked for dimensional accuracy, and then it was furnace preheated to 600 F to avoid possible weld cracking. The assembly was loaded on an outboard, track-guided positioner, pushed into the vacuum chamber, and aligned under the gun. After pump-down, the weld was made in about 45 sec, using the welding conditions given in the table with Fig. 33. A furnace postheat at 600 F was followed by visual and dimensional inspection.

This procedure was repeated for each joint, in the following order: 1 to 2, 3 to 4, 4 to 5, and 2 to 3. Before final machining, the welds were machined flush and inspected by magnetic-particle methods. After final machining, the shafts were dynamically balanced.

Use of Scanning

Scanning is a method of checking the runout between the beam spot and the joint to be welded. Its purpose is to indicate the final adjustments needed to align the beam with respect to the joint and to expose possible unsuspected discrepancies in beam behavior or workpiece travel that would interfere with welding. Details of the procedure vary with joint design and the type of equipment available; in one widely used method, a low-power beam is used for visual scanning of the joint during a simulated welding pass.

Accuracy of Beam Alignment. Beam alignment is generally a matter of workpiece alignment, as even guns of the adjustable type are usually fixed during welding. Where the gun does traverse the joint, the principles of alignment are the same. Most joints are designed for simple path shapes — straight lines and circles — that can be adequately traced with precision-made carriages, cross-feeds, turntables, eccentric tables and spindles.

General Procedure for Scanning. The workpiece is fixtured, and the joint is aligned for travel direction and is moved to its approximate location under the gun. The chamber is closed and pumped down to a vacuum sufficient for safe operation of the gun. A low-power beam is turned on and focused sharply on the workpiece surface. The specific power settings will vary with the working distance selected and the power ratings of the machine; however, they should be sufficient only to create a detectable spot without overheating the workpiece.

The joint line is then adjusted to its precise location with respect to the beam spot, the workpiece is traversed through a complete cycle, and the runout is equalized. Maximum allowable tolerance on runout is determined from a consideration of joint design and weld width, which is mainly a function of the spot size and travel speed.

Considerable latitude in required accuracy of alignment can be gained where beam oscillation can be used. Usually, if the runout approaches one-half the effective welding-beam spot width (spot size plus oscillation amplitude), the cause must be determined and corrected. If the runout is within tolerances, production parts ordinarily need only periodic scanning as a quality control measure.

Problems in Scanning. Some of the causes of excessive runout and other difficulties encountered during scanning are as follows:

1. Poor joint design; inaccurate joint preparation
2. Improper fit-up; inadequate fixturing
3. Lack of precision in workpiece traversing mechanism
4. Obstructions in the beam path
5. Indistinct or undetectable joint line
6. Beam deflection by electric or magnetic fields.

The corrections required for mechanical discrepancies are self-evident; the effects of electric and magnetic fields may be less obvious.

The negatively charged electrons that comprise the electron beam constitute a negative space charge. When the electrons strike an insulated metal part, negative charges are built up, causing mutual repulsion between the part and the beam. By grounding the part, excess electrons are conducted away. Example 482 describes the use of aluminum foil for this purpose.

To avoid unintentional deflection of the beam by nearby magnetic fields, workpieces, fixtures and tooling components made of magnetic materials should be demagnetized before welding, as described on page 521.

Scanning techniques vary in detail, depending on the type of equipment used and also on joint design. It is not always necessary to position the beam spot precisely on the joint line. When welding dissimilar metals, dissimilar thicknesses of the same metal, or certain self-locating joints, it is often necessary to position the beam a short distance from the visible joint line. A corner edge or a scribed line can often serve as a reference, or measurement can be made with an optical grid.

Some special-purpose electron beam welding machines are not intended for scanning. Nearly all general-purpose machines, however, make some provision for this operation. On machines with a fixed gun located in an upper section of the vacuum chamber, a built-in, internal, optical viewing system is generally provided for scanning. Machines having movable guns can be equipped with external telescopes and internal mirror systems.

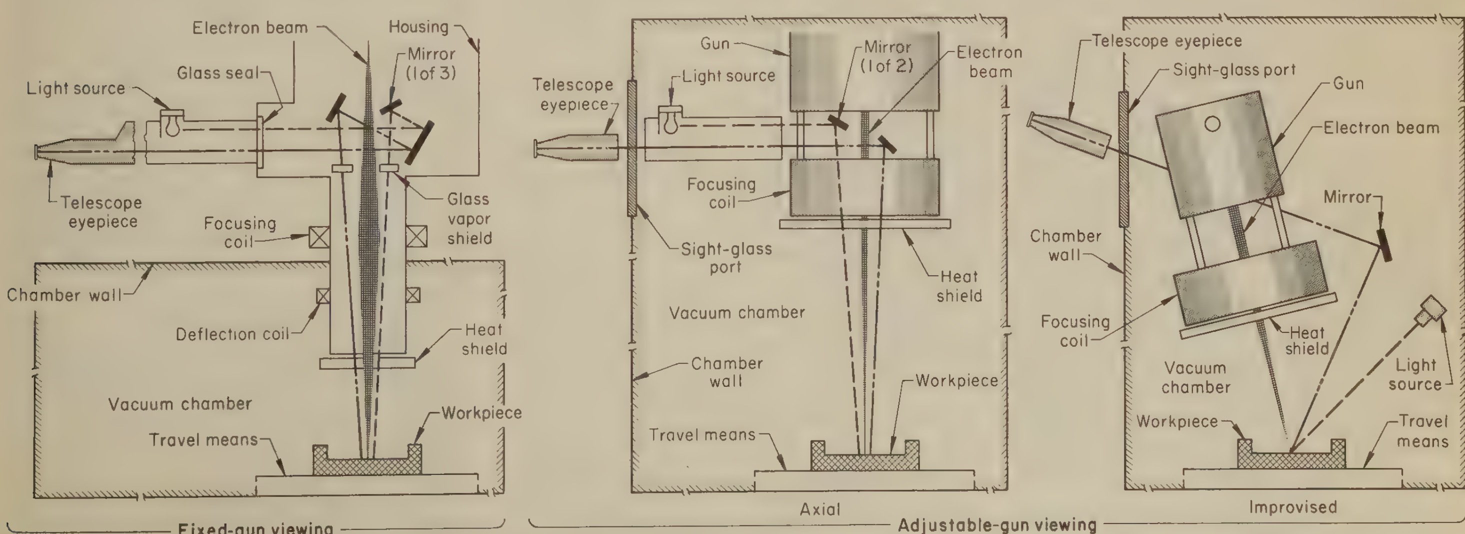

Fig. 34. Three types of viewing systems used to scan the joint for beam alignment and to observe the joint during welding

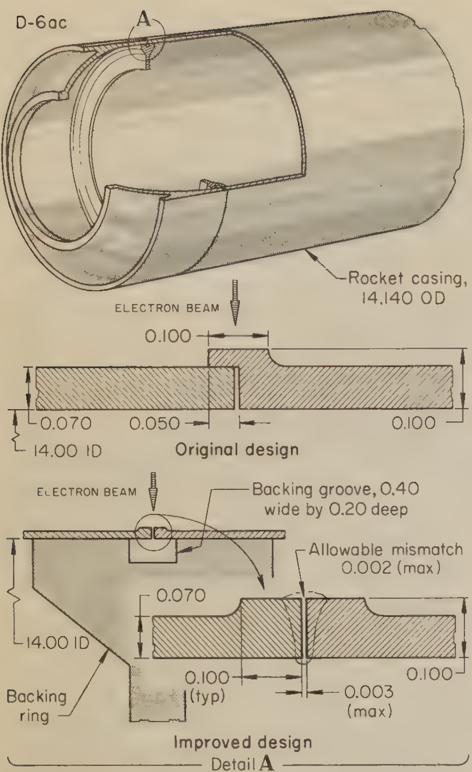


Joint type	Circumferential butt
Weld type	Square groove, integral filler-metal shoulders
Machine capacity	150 kv at 40 ma
Gun type	Fixed
Vacuum-chamber size	48 in. in diameter, 72 in. long
Maximum vacuum	10^{-5} torr
Fixtures	Holding jig; lathe-type positioner
Welding power:	
First pass	120 kv at 2 to 3 ma
Second pass	120 kv at 8 ma
Welding vacuum	10^{-4} torr
Working distance	10 in.
Beam spot size	About 0.03-in. diameter
Beam focal point	At work surface
Welding speed	44 ipm
Number of passes	Two
Pieces per load	One
Pumpdown time	8 min
Postweld heat treatment	Furnace stress relief

Fig. 35. Aft end of a rocket casing, showing original joint design and improved design that permitted optical scanning for accurate beam alignment (Example 484)

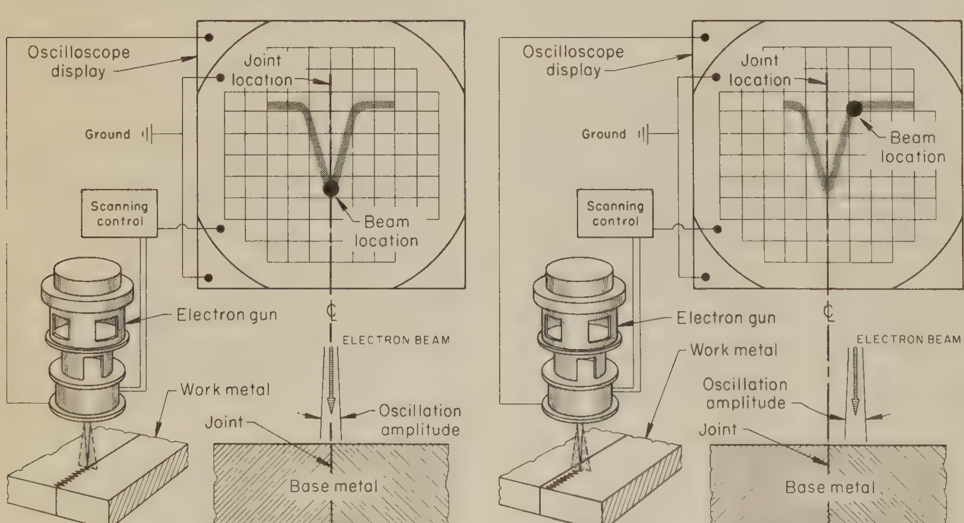
Optical Scanning. Optical systems usually consist of horizontally mounted monocular or binocular telescopes with internal illumination and reflecting mirrors that provide a line of sight coaxial with the beam path. Other viewing directions can also be improvised. Magnifying power may be 10 to 40 times, depending partly on working distance. High-precision alignment can be obtained. The optics of fixed-gun and adjustable-gun viewing systems are shown schematically in Fig. 34.

There are two common methods of using this equipment. One method makes use of a low-power beam that is sighted telescopically on the workpiece surface. Using a calibrated grid, measurements to 0.001 in. can be made. In the other method, the beam is centered on a crosshair reticle embodied in the optical system. The beam is then turned off and the workpiece joint is moved into coincidence with the crosshair, under internal illumination. The advantage of the latter method is that, after the beam is turned off, the chamber need no longer remain under vacuum, and further alignment work can be done in the open, if necessary.

On some machines, the gun chamber can be sealed off when the gun is inoperative. The method of transferring beam alignment by means of the crosshairs was used in Example 482 (low-power scanning was not needed). The full-power beam was focused on a tungsten target held at the exact focal length desired for the final operation.

Before scanning, the mirror surfaces of the internal optical system should be cleaned, because vapor deposition takes place during welding. The frequency of cleaning may vary from a few to many hours of operation, depending on the amount of vapor created and the proximity of the weld. Mirror surfaces are usually protected with glass shields that can be removed for cleaning or replacement.

A scanning operation that resulted in a change in joint design, and indicated the need for demagnetization of the workpiece, is described in the following example.



(a) Electronic scanning setup, beam on joint (b) Electronic scanning setup, beam displaced to right of joint

Fig. 36. Arrangement for electronic scanning of a joint, showing equipment, joint to be welded, and oscilloscope display (a) *with the beam centered on the joint and* (b) *with the beam displaced to the right of the joint*

Example 484. Scanning as Related to Joint Design and Effect of Residual Magnetism in Welding D-6ac Steel (Fig. 35)

A 14-in.-diam rocket casing made of D-6ac alloy steel was designed with a circumferential joint to be electron beam welded. Figure 35 shows the general location of the joint, together with a schematic representation of the internal fixture that was used to obtain accurate self-alignment and to confine spatter, rather than to provide a backing for the weld. In setting up for electron beam welding, three features of the procedure came under close review, namely: (*a*) joint design, (*b*) scanning technique, and (*c*) stray magnetic fields, which caused irregular beam deflection.

Joint Design. At first, the joint shown as the original design in Fig. 35 was considered, because its self-locating characteristics would eliminate the need for a fixture to provide close alignment of joint surfaces. This design was rejected because of difficulty in centering the beam accurately on the joint line. To permit satisfactory scanning of the joint prior to welding, and adequate visibility during the welding operation, the improved design (Fig. 35), which also provided integral filler metal to allow for final finishing, was adopted.

Scanning. In setting up the welding procedure, the last operation before welding was the scanning of the joint with a low-power, focused beam to align the joint with the beam. A small incandescent spot was generated on the fixtured, rotating workpiece, which was positioned so that the spot coincided with the visible line of the joint. This operation was performed by remote control during or after pumpdown, because gun components would deteriorate quickly if operated in air. Observation of the runout of the joint line with respect to the beam spot was made with a 16-power telescope optically arranged for viewing directly down the beam path.

Beam settings for scanning were controlled less closely than those for welding. Scanning settings used were: (*a*) beam power, 90 to 110 kv at 1.0 ma; (*b*) working distance, 10 in.; (*c*) beam focal point, sharp on work surface.

The scanning technique indicated the adjustments needed for beam alignment, and also identified areas where the beam was deflected by stray magnetic fields.

Stray Magnetic Fields. During scanning trials, erratic beam deflections were observed at several points on the casing. Although the amount of deflection was small at the low beam power of scanning, it would increase considerably under full welding power. It was found that the steel casing components had been magnetic-particle inspected after machining, and had retained some of the induced magnetism.

Demagnetization was made a standard procedure for all casing components. This was done by removing the parts slowly from within the magnetizing coil of the magnetic-particle testing machine after testing was completed. The parts were then degreased and checked for residual magnetism with a magnetic-field indicator. Just prior to welding, when it was already in the welding chamber, the assembly was again checked (in the same way) for magnetic fields. The steel fixturing used was demagnetized at the outset of the production run, and, although periodically checked, did not require further demagnetization in the run. After all corrections were made, final runout during rotation was estimated to be within ±0.006 in. max.

Having established the proper conditions for welding, a trial run was made to determine the actual settings for production welding. The weld was made in two passes by rotating the casing under a fixed beam centered vertically on the joint. The first pass was made at low power to hold the parts firmly in place for the second, or penetrating, pass. No cosmetic pass was made, because the weld was later to be machined flush. Neither preheat nor any special beam oscillation technique was used. At the completion of welding, current

was downsloped over an additional 5° of revolution. Machine settings and other welding conditions are summarized in the table accompanying Fig. 35.

After welding, casings were furnace stress relieved. The joint was machined and the entire casing was grit blasted. Before applying a final hydrostatic test, the joints were completely examined by x-ray and magnetic-particle inspection.

Scanning Without Optics. Scanning can also be done without visual aids where great precision is not required. On machines that are not equipped with viewing optics, scanning is done by direct observation through sight-glass ports. From one to four such ports may be located in the chamber wall, usually spaced 90° apart, to permit checking beam alignment from several angles. The beam spot is generated the same as for optical scanning.

Electronic Scanning. Checking the location of an electron beam with respect to the joint can be done with an electronic device that displays the relationship on an oscilloscope. The equipment makes use of a low-power electron beam that is made to oscillate at 60 hertz transversely across the joint. The amplitude of the oscillation is sufficient to display the workpiece surface for a short distance on either side of the joint, as well as the joint line itself. In addition, each oscillation pulse is interrupted momentarily to permit the beam to assume its normal welding position, causing a relatively large spot to appear on the display. When the spot coincides with the joint line of the display, the beam is accurately aligned for welding.

Figure 36(a) shows the display condition for a beam centered exactly on the joint. The V represents the joint line, with the beam spot centered accurately; the two horizontal arms (of equal length with a centered beam) at the top of the V represent the adjacent workpiece surface. The broken lines above the work (at left in Fig. 36a) show the plane of oscillation; the wavy line along the joint in the same view shows the approximate amplitude of oscillation.

If the beam location were displaced to the right of the joint, the display would look like Fig. 36(b); an opposite-handed display would indicate displacement to the left. By the relative depth of the V, the display also indicates the amount of joint separation from apparent zero to approximately 0.006 in. A joint mismatch of a few thousandths inch is indicated by the relative height of the horizontal arms.

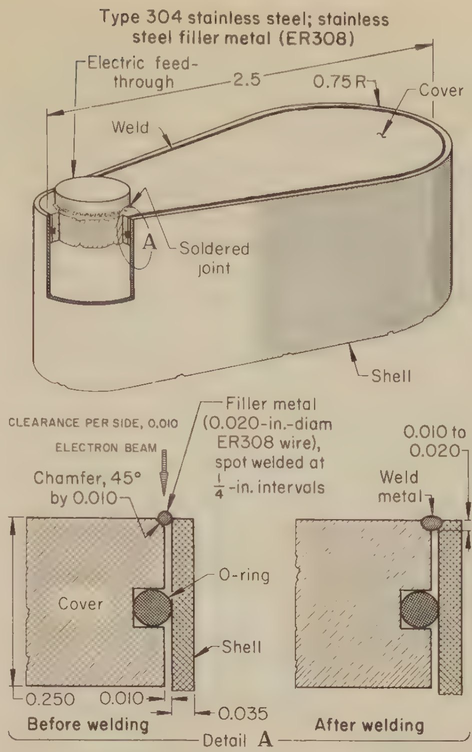
In setting up for electronic scanning (under vacuum), the work is provisionally aligned as for optical scanning, making sure that the joint line is parallel to the direction of travel.

Joint Tracking

Joints that have a path that deviates from a straight line or circle usually require an automatic tracking device for electron beam welding of production quantities. For small production lots, manual tracking, using a coordinate drive having separate controls, sometimes can be used. Whether the method is controlled manually or automatically, the motion required to generate the curve is usually imparted to the workpiece, although limited motion can be imparted to some guns.

Manual Joint Tracking. In manual tracking, the welding operator must closely observe the joint at the point where the weld is being made, to anticipate any change in direction. The conditions best suited to this type of operation are: (*a*) a joint path consisting of a smooth curve, (*b*) slow travel speed, and (*c*) a low-power beam with oscillation, to form as wide a weld as possible. The welding operator is capable of regulating two motions of the workpiece (or gun) by manually adjusting the remote controls of the travel mechanism.

For a low heat input, to permit the use of the low welding speeds needed when manual tracking is used, beam pulsation can be combined with beam oscillation, as described in the following example.



Joint type	Irregular, circumferential edge
Weld type	Seal, with preplaced filler metal
Machine capacity	120 kv at 25 ma
Gun type	Triode; fixed; with tungsten hairpin filament
Vacuum-chamber size	23 by 36 by 36 in.
Maximum vacuum	10^{-6} torr
Fixtures	Copper chill; rotating positioner; horizontal table with x-y motion
Filler metal	0.020-in.-diam ER308
Working distance	6 in.
Beam focal point	Sharp at work surface
Welding power	100 kv at 3.5 ma
Welding vacuum	10^{-4} torr
Beam pulsation	100 hertz, 2-millisecond pulse length
Beam oscillation	Circular, 60 hertz, 0.029-in. amplitude
Joint tracking	Manual
Tracking speed	2 to 3 ipm

Fig. 37. Top portion of a reusable electronic enclosure showing the seal weld that was made with a pulsed and oscillated beam, allowing the use of low welding speed for manual joint tracking. The small weld and thick cover plate permitted the seal to be machined off and rewelded. (Example 485)

Example 485. Use of a Pulsed Beam To Permit Low-Speed Manual Joint Tracking in Making a Seal Weld Designed for Removal and Rewelding (Fig. 37)

The problem of sealing an electronic enclosure designed for repeated reuse was solved by developing a manual, pulsed electron beam welding technique. The portion of the device involved in the sealing operation is shown in Fig. 37 as consisting of a 0.035-in.-thick shell and an irregularly shaped, 2.5-by-1.5-by-0.250-in. cover plate, both of type 304 stainless steel.

Designing for reusability resulted in three special features of the joint. The cover plate was made thick to permit machining off and rewelding the seal many times during the life of the device. To obtain adequate sealing with the least loss of material and time in machining, weld penetration was specified as 0.010 to 0.020 in. A joint clearance of 0.010 in. between the cover plate and shell was provided for easy removal of the cover, but this clearance made it necessary to use a preplaced filler-metal wire, as shown in detail A of Fig. 37.

Other special aspects of part design determined details of the welding procedure. An O-ring seal was placed in the joint to prevent metal vapors generated during welding from contaminating the internal mechanism. The soldered joint of an electric feed-through passed close to the weld joint, requiring low heat input in welding. The oval configuration of the joint made manual joint tracking necessary — the few parts required made it impractical to construct an automatic tracking tool. Adding to the difficulty in tracking was an internal magnet, which caused beam deflection.

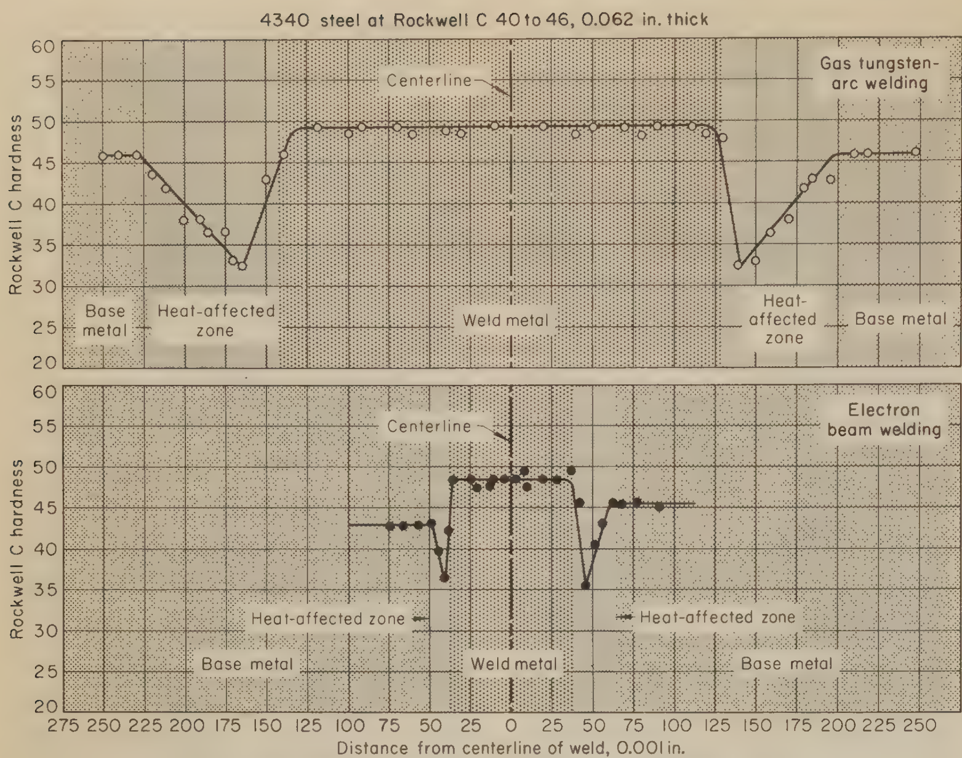
To obtain low heat input, a heavy copper chill (not shown) was built to encase the shell. To reduce the speed of welding to a level enabling the welding operator to track the joint, the electron beam was energized in pulses and was circularly oscillated, while the gun remained in a fixed vertical position.

Before welding, the joint was wiped clean with a solvent, the components were assembled, and chill blocks were attached. Filler-metal wire was placed in the beveled groove of the joint and was capacitor-discharge spot-weld tacked at ¼-in. intervals. The assembly was then mounted on a positioner to rotate about a vertical line that intersected the midpoint of the axis of symmetry of the cover plate. The rotating positioner, in turn, was mounted on a horizontal table (in the vacuum chamber) equipped with x-y motion control. Both rotation and horizontal x-y motion could be independently controlled by the operator. However, in welding, only rotation and horizontal y-motion (toward and away from the operator) were used. Observation of the joint was made by telescope.

After pumpdown and beam alignment, the part was rotated to produce tangential speeds of about 2 to 3 in. per minute while the part was moved back and forth to hold the beam on the joint. Welding was accomplished in one pass, using the machine settings and other welding conditions given in the table accompanying Fig. 37.

Automatic Joint Tracking. Mechanical, electromechanical, numerical-control, and computerized systems are sometimes used for welding joints that deviate from straight lines or circles.

Devices that track the joint by using a stylus or follower wheel as a probe are limited in their applicability to electron beam welding. The probe provides transverse motion as the workpiece rotates or travels longitudinally. This type of probe requires a groove in or parallel to the joint, or an edge that duplicates the joint contour. For tightly fitting, flush butt joints, a groove may be cut along the joint. Natural tracking surfaces can be provided by edge, lap, T and corner joints.



Rockwell C hardness was obtained by converting microhardness readings taken on cross sections of the welded joints at their midpoints after stress relief at 650 F.

Fig. 38. Hardness traverses across electron beam (high-vacuum) and gas tungsten-arc welded butt joints in 0.062-in.-thick quenched-and-tempered 4340 steel

If the probe rides in the joint, it must precede the beam, to avoid heat damage and spatter; its response to a change in direction is therefore early with respect to the response of the beam spot. Probes that ride an edge or surface that duplicates the curve of the joint can often be placed abreast of the beam spot. However, the minimum radius that can be translated depends on the diameter of the stylus or wheel. Probes can induce translation mechanically or electromechanically.

Mechanical Joint Tracking. The limitations of the mechanical probe can sometimes be overcome by using the workpiece itself as a follower. For instance, in Example 485, the positioner spindle could have been spring-loaded so as to cause the workpiece shell to bear against a fixed roller. The moving joint would remain in constant relation to a fixed beam at the point of contact with the roller, and there would be no delay in response time. Welding speed could be controlled by varying the rotational speed of the spindle.

The use of a template to obtain transverse motion by pantograph or equivalent linkage introduces several undesirable variables, namely: (*a*) the above-mentioned limitation on follower diameter, (*b*) loss of precision because of play in the linkage, (*c*) delay in response time for the same reason, and (*d*) the problem of superimposing the generated motion on a pre-existing path. Either the workpiece table or the gun would have to float freely in the transverse direction. Another consideration is the space occupied by the equipment in relation to the size of the vacuum chamber.

Electromechanical joint tracking systems make use of a probe equipped with left-hand and right-hand transducers that create an electrical signal when the probe is displaced in these (transverse) directions. The signal is relayed to servomotors, which operate to move either the gun or the workpiece table in the direction that will reduce the signal to null. Because these probes track in the groove or along an edge of the joint, the signal can be early, but there is no problem as to superimposing independent paths. Precision is usually better, response-delay time is shorter, and other problems associated with mechanical tracking with templates are avoided.

Tape-Controlled Joint Tracking. Workpiece (or gun) motion can be programed for the complete welding cycle by conventional numerical-control equipment. The actual position of the workpiece with respect to the programed tape input can be controlled to approximately ±0.001 in. As with other tracking systems in which the generated motion is independent of the joint path, the two paths must coincide. There must be a high degree of assurance that the prior processing of the workpiece, its fixturing, and beam alignment have been done with repeatable accuracy. The tape input information must be sufficiently fine to generate the curve with the desired accuracy.

Computerized joint tracking can be used in a manner that is analogous to numerical control.

Beam Oscillation

On machines equipped with deflection coils, oscillation (as well as static deflection) can be imparted to the beam by a separate control circuit. Beam oscillation is used to perform a number of useful functions. Oscillatory motion is usually circular or rectilinear (straight-line), the latter being either transverse or longitudinal with respect to joints aligned on the x-axis or y-axis. Amplitudes (full sweep) of ¼ in. or more are possible, but those commonly used range from 0.010 to 0.125 in., with frequencies from 35 to 1000 hertz.

Beam oscillation is used to produce wider welds, slower cooling rates, and more uniform weld shape, without necessarily defocusing the beam. Accuracy in beam alignment and joint tracking is less critical.

Welds somewhat wider than normal are required in joints that have relatively large root openings, or that make use of filler-metal preplacements, as in Examples 475, 485, 493 and 494 in this article. Oscillation was used in these applications and in bridging the three-member joints in Example 469.

Lower cooling rates that result from larger welds permit more outgassing from materials containing impurities, and thus help to control porosity. Welds made in metals subject to embrittlement during or after fast cooling can benefit from beam oscillation and defocusing, as described in Example 503.

One of the more useful effects of oscillated beams, as compared to stationary beams, is the general improvement of weld shape. Oscillation with or without defocusing has been used to avoid excessive undercut and underfill, as described in Examples 477, 491 and 495.

Uneven penetration in partial-penetration welds is undesirable and sometimes intolerable because of the possibility of melt-through. Beam oscillation in Examples 492 and 503 helped to reduce variability in penetration depth at the root of the weld. The added assurance of better process control was sufficient reason for using oscillation in Example 496.

Beam oscillation is not always used, even though available. Except for penetration control, most advantages can usually be duplicated by using defocused beams. Also, the wider weld and greater heat input may be a disadvantage, as in welding thin foils.

Use of a Pulsed Beam

Beam operation can be changed from continuous to intermittent on machines equipped with pulsing controls. Although available repetition rates (frequencies) and pulse lengths depend on the control unit, frequencies in the range of 0.1 to 3000 hertz with pulses up to about 60 or 70 milliseconds in duration are representative. Beam pulsation reduces the rate of heat input, but is independent of other beam conditions. Therefore, pulsation can be combined with oscillation and deflection, as well as travel speed, to influence weld behavior (see Example 483).

At very low frequencies, such as 1 hertz, with a 5 to 10 millisecond pulse length, each pulse produces a separate weld, even at low travel speed. By increasing travel speed and adjusting pulse frequency and pulse length, tack welds, spot welds, or intermittent welds can be made at normal production rates. Increasing pulse frequency to approximately 35 to 100 hertz while

maintaining short pulse lengths makes it possible to overlap the successive welds to form a continuous weld at speeds suitable for manual tracking.

Pulsed beams generally result in lower peak temperatures, especially in the area adjacent to the weld, as compared to continuous welding, although total heat input may be greater because of the slower welding speed used. At higher pulse frequencies, pulsation has been used to control the solidification pattern of the weld and the microstructure of the heat-affected zone. Pulsation also has been used in rewelding to fuse cold shuts, fill gas pockets, and smooth irregular root areas.

Repair and Planned Salvage

Electron beam welding is used to make welds for repair or planned salvage that would be impossible or excessively slow and costly by any other method. The application of electron beam welding to repair applications is found in Examples 479, 480, 488 and 494, and mentioned in Example 476.

Weld joints that were designed for planned salvage are described in Examples 485 and 489.

Electron Beam Brazing

Electron beam welding equipment and techniques have been used to a limited extent for brazing. The high vacuum used in the work chamber (10^{-4} to 10^{-5} torr) permits adequate flow of the brazing filler metal in properly cleaned joints without using reducing atmospheres or fluxes (see Example 631 in the article on Brazing of Stainless Steel).

Welding of Low-Carbon Steel

Low-carbon steels are readily electron beam welded. Grain size in both the weld and the heat-affected zone is significantly smaller than in arc welds, because of the lower heat input and extremely rapid heating and cooling.

Rimmed steel causes excessive gassing. A technique used to weld rimmed steel is to sandwich an aluminum alloy shim about 0.010 in. thick in the joint to provide deoxidizing action during welding, as described in the subsection on Preventing Porosity, page 539. Welding at a low travel speed or otherwise adjusting welding conditions to produce a more tapered weld and thus to allow more time for the escape of gases from the molten weld metal also helps to reduce porosity.

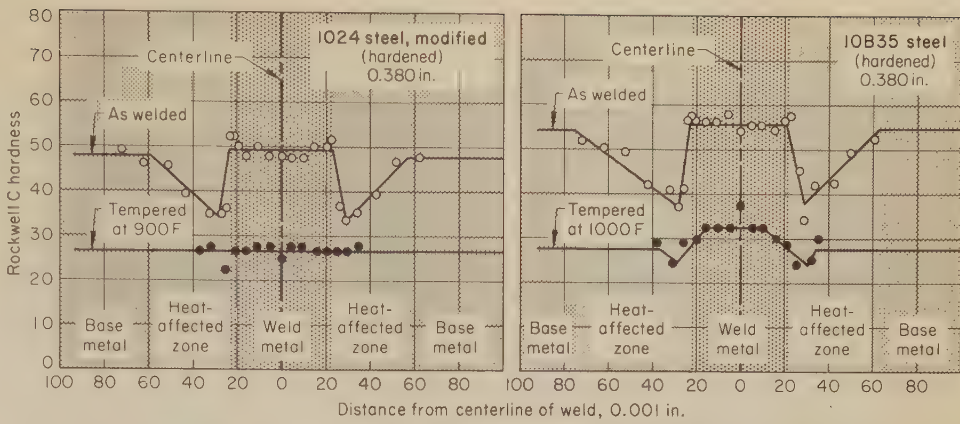
Semikilled steel is easier to weld than rimmed steel, but some oxygen may remain to cause porosity. Fully killed steel is readily weldable.

Applications. Aluminum-killed 1017 steel 0.070 in. thick was butt welded by the nonvacuum electron beam process in mass production in Example 467.

Low-carbon steel was electron beam welded to other base metals in Examples 470 and 498.

Welding of Hardenable Steel

The variation in weldability by the electron beam process among hardenable steels follows the same pattern as for



Rockwell C hardness was obtained by converting microhardness readings taken on cross sections of the welded joints at their midpoints.

Fig. 39. Hardness traverses across electron beam (high-vacuum) welded butt joints in 0.380-in.-thick heat treated 1024 (modified) and 10B35 steel, as welded and as tempered

arc welding these steels. Properties of electron beam welds in a given hardenable steel differ from those of arc welds mainly because of the narrowness of the fusion and heat-affected zones and the extremely rapid heat-melt-cool cycles.

Hardness traverses across the midpoint of electron beam (high-vacuum) and gas tungsten-arc welds in 0.062-in.-thick heat treated 4340 steel are plotted in Fig. 38. For both welds, maximum hardness was produced uniformly in the weld metal, and hardness dropped off abruptly at the edge of the weld metal.

Similar hardness traverses for electron beam welds in 0.380-in.-thick heat treated 1024 (modified) and 10B35 steel are shown in Fig. 39. The hardness profile across these two welds was similar to that for the electron beam welds in 0.062-in.-thick 4340 steel. Tempering after welding eliminated or minimized the hardness differential in the heat-affected zone (Fig. 39).

Prevention of Cracking. Cracking can be a problem in electron beam welding of hardenable steel, just as in arc welding, if the weld is made in a highly restrained joint, especially in welding parts that have been hardened. Deep circular welds in heavy sections are particularly troublesome. Partial-penetration welds are more likely to crack under restraint than full-penetration welds. It is desirable to place the joint in a location that will allow the part to shrink freely as it cools after welding.

Welding through carburized or nitrided cases is not recommended.

Cracking of electron beam welds in hardenable steel can also be minimized by: reducing the welding speed to allow more buildup of heat in the base metal; preheating; postheating; and allowing the work to cool in the chamber after welding, for slower cooling.

Medium-carbon steels, except for the free-machining types, are readily electron beam welded (for hardness traverses, see Fig. 39). Weldability decreases with increasing carbon content.

Example 470 describes the electron beam welding of hardened 1042 (at Rockwell C 57) to 1019 steel. In Example 468, Hastelloy W filler metal was used to prevent cracking.

Low-alloy steels containing less than 0.30% carbon are usually electron beam welded without preheating or postheating. When preheating is used, as to prevent cracking in highly restrained joints, a temperature of 500 to 600 F is usually adequate. If the part has been hardened and tempered prior to welding, the postweld tempering must be done at a temperature slightly below that at which the base metal was originally tempered.

Two of the most frequently electron beam welded alloy steels of this type are 8620 and 9310. Components made of these steels often are case hardened, then are assembled by electron beam welding, without distortion or heat damage to the case. Before welding, the case should be removed from the immediate vicinity of the joint, to avoid microcracking of the case.

In Example 465, a case-hardened 8620 steel shaft was assembled with a 0.180-in.-deep circumferential weld to a heat-resisting alloy casting, to make a supercharger impeller. Examples 504 and 505 describe the electron beam welding of case-hardened 9310 steel.

High-strength alloy steels containing more than 0.30% carbon are electron beam welded either in the annealed or the normalized condition or in the quenched and tempered condition, although weldability is better for the annealed or normalized condition. The hardness profile for electron beam welds in hardened high-strength alloy steel sections no thicker than about ¼ in. is ordinarily like that shown for 0.062-in.-thick heat treated 4340 steel in Fig. 38, and joint strength can approach that of the base metal, without preheating or postweld treatment other than stress relief.

In electron beam welding thicker sections of high-strength alloy steels, preheating or postheating, or both, is usually needed to prevent cracking. In studies on full-penetration, single-pass welding of 0.6-in.-thick annealed D-6ac steel, cracking was observed when preheating was not used, and was eliminated by preheating at 1000 to 1050 F. Welding was started with the joint at a temperature of 700 F, and the joint temperature remained above 650 F for 8 to 10 min after completion of the weld. Hardness profiles for the joints welded with and without preheat are shown in Fig. 40. Sound welds were also obtained in 2.2-in.-thick annealed

D-6ac steel, after preheating to 800 to 850 F, starting welding when joint temperature was no lower than 500 F.

In the example that follows, hardened D-6ac steel 0.030 in. thick was welded without preheating; the weldment was tempered at 1000 F.

Example 486. Welding of Hardened D-6ac Alloy Steel With Average Joint Efficiency of 95% (Fig. 41)

In making missile cases 8 in. in diameter by 48 in. long from D-6ac steel, hardened-and-machined head closures were joined to 0.030-in.-thick shell cases that had been ausform-strengthened by power spinning. Welding was done without preheat and, as shown in Fig. 41, the beveled edges provided a self-aligning joint, requiring only end-thrust tooling during welding.

The table with Fig. 41 lists the principal welding conditions, and section A-A shows the extent of fusion obtained. The weld reinforcements resulted from upsetting of the restrained base metal. Welding was done in three penetration passes and one cosmetic pass; no filler metal was used.

Postweld heat treatment consisted of tempering at 1000 F. Tests on transverse joint specimens showed an average tensile strength of 249,000 psi, with an average joint efficiency of 95%.

A total of ten cases was produced.

Electron beam welding was selected in preference to arc welding, for the following reasons (see also Example 500):

1 Base-metal properties were not decreased significantly in welding.
2 Preheating was unnecessary.
3 Rigid backup tooling was not required.
4 Finish-machined components were welded without excessive distortion.
5 Self-aligning joints simplified fixturing.

Applications similar to Example 486 are described in Example 500, in which a cost comparison is given for electron beam welding vs gas tungsten-arc welding, and Example 484, in which the work-metal thickness was 0.100 in. Other applications involving high-strength alloy steel are described in Examples 464, 471, 483 and 503.

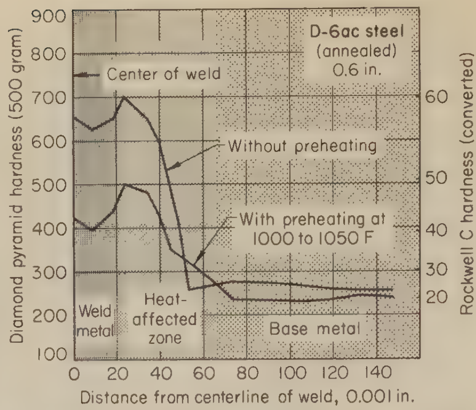
High-Carbon Steels. Because of the low total heat input and the rapid thermal cycling that are characteristic of electron beam welding, weld cracking of steels containing more than 0.50% carbon is less likely than in arc welding. Even high-carbon alloy steels such as 52100, which are seldom arc welded, have been electron beam welded on a high-production basis, with more than 400,000 welds made annually on some parts. The 52100 steel is welded in the spheroidize-annealed condition in applications where joint performance is not critical to the function of the part, and service stresses in the joint are low. Preheating and postheating are necessary.

In the example that follows, initial difficulties were encountered in electron beam welding a simple circular joint in 52100 steel to a depth of 0.145 in.

Example 487. Change in Joint Design and Use of Slow Cooling To Prevent Cracking of Welds in Medium-Vacuum Welding of 52100 Steel (Fig. 42)

Attempts to weld two bolting lugs of 52100 steel to an aircraft control housing of the same material resulted in cracking. The weld joints were located in an area that would be lightly stressed in service. The material was procured and welded in the spheroidize-annealed condition, and the part was hardened after welding.

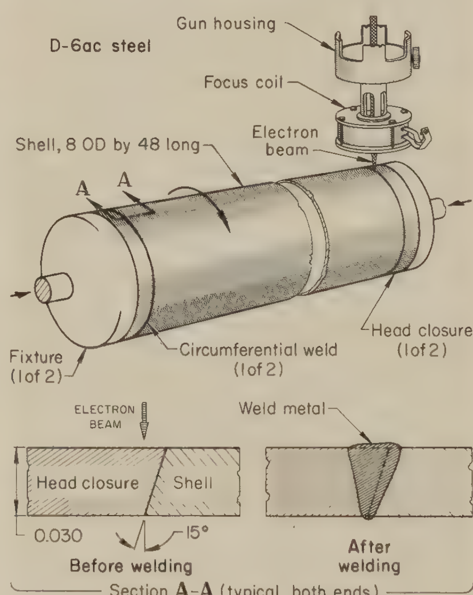
The original design, which required welding the two lugs to the shell along approximately 90° arcs of contact, is shown at the left center in Fig. 42. Carefully machined and cleaned parts were assembled in a fixture similar to the one shown at the top in Fig. 42, to maintain a nominal joint clearance of 0.0005 in. The joints were electron beam welded, without preheating, in a single pass by rotation under a beam with a fixed operating position.



Hardness traverse across midpoint of electron beam (high-vacuum) welded butt joint in 0.6-in.-thick annealed D-6ac steel, as-welded, with no preheat and with preheat at 1000 to 1050 F

Fig. 40. Effect of preheating on hardness

When cracking resulted, a new design and procedure were developed, to reduce and balance shrinkage stresses and to obtain a lower cooling rate. The lugs were replaced by a circular ring (Fig. 42, right center, and detail A). Because of its symmetrical shape, the ring was judged to be less susceptible to cracking than the lugs had been. Instead of a joint clearance, an interference fit of 0.0006 in. max was specified, to reduce residual shrinkage stress. In addition, a preheating, welding and postheating procedure was adopted that retarded cooling after welding.



Joint type	Circumferential butt
Weld type	Slant groove
Machine capacity	30 kv at 500 ma
Gun type	Pierce; fixed
Welding power	20 kv at 25 ma
Welding vacuum	5×10^{-5} torr
Welding speed	39 ipm
Fixture	Lathe-type positioner
Preheat	None
Postheat	Tempered at 1000 F

Fig. 41. Missile case and lower portion of electron gun column as set up for welding in a vacuum chamber (Example 486)

Before assembly, the joint surfaces were ground for dimensional accuracy. Cleaning was done by one dip and two sonic immersions in solvent. Where necessary, the joint surface of the ring was polished with fine abrasive. The interference fit was made by heating the ring to 350 F and pressing it in place before the entire assembly was preheated. The assembled fixture was fitted on a turntable for rotation. Beam alignment and settings were made in the conventional manner. Details of the machine settings and other welding conditions are summarized in the table with Fig. 42.

Preheating consisted of heating the assembly to 350 F before fixturing. To lengthen the heat cycle during welding, a short current upslope was used, and full welding power was applied for two passes (revolutions). Power was then downsloped to zero for $1\frac{1}{4}$ revolutions, making a total of $3\frac{1}{4}$ revolutions for the complete welding cycle. The lengthened heat input provided uniform joint temperature, and the downslope retarded cooling in the weld area. One part was welded per chamber load; within minutes after the chamber was opened, the part was placed in a furnace for stress relieving at 1200 F for 1 hr.

As shown in detail A of Fig. 42, joint penetration exceeded the thickness of the ring flange. To ensure full penetration of the 0.090-in. thickness of the ring on the finished assembly (after machining), and to avoid possible root porosity at the level of the finished ring, the weld was made to exceed the 0.145-in. minimum depth.

The preheating and postheating passes, plus the improved design and the interference fits, were credited with eliminating the cracking that had previously occurred immediately after welding. Postheating reduced the hardness of the weld to about Rockwell C 40. Without heat control, weld hardness had reached Rockwell C 57. After machining, the housings were hardened, finish machined, and ultrasonically inspected. No cracks were permitted.

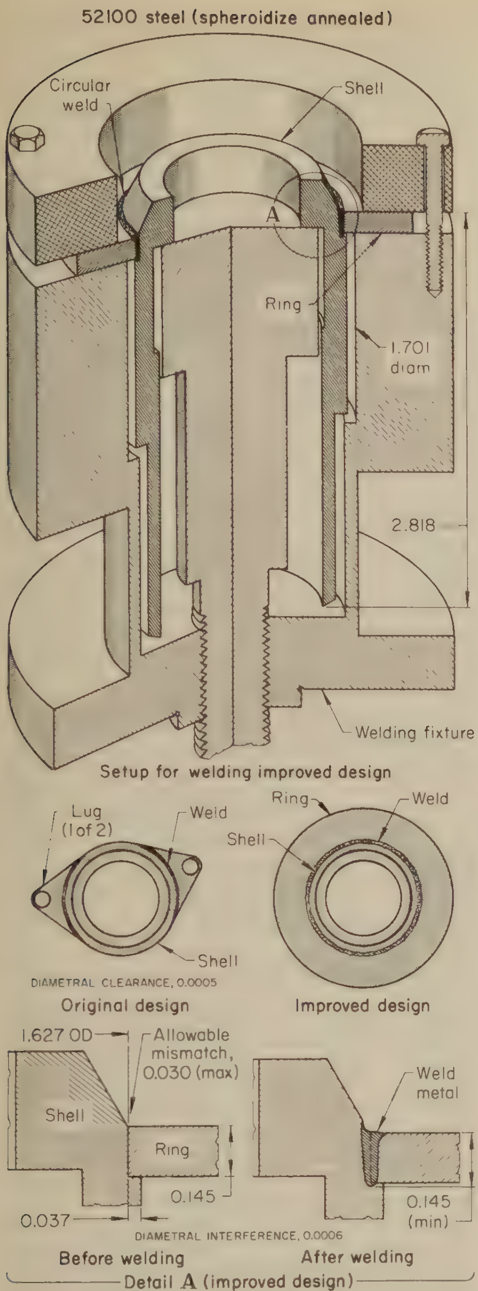
Welding of Tool Steel

The chief advantage of electron beam welding over other welding processes in joining tool steels is its ability to produce joints at high speed without annealing or other heat treating operations. Hardness profiles similar to those shown for low-alloy steels in Fig. 38 and 39 were also obtained for H11 tool steel. For full-penetration butt welds on hardened (Rockwell C 50) sections 0.225 in. thick, the hardness of the weld metal and the immediately adjacent base metal was Rockwell C 56 to 57, and hardness dropped to a minimum of Rockwell C 43 to 46 in the heat-affected zone, as measured after double tempering at 1025 F. The overtempered portion of the heat-affected zone was only 0.005 in. wide.

Small dies of D2 tool steel have been electron beam welded in production. A larger operation is the production of bimetal band saws. Specially designed medium-vacuum machines are used to produce band-saw blades by welding $\frac{1}{16}$-in.-wide M2 high speed steel cutting-edge strips to 6150 steel bands. The composite blade is about $\frac{1}{32}$ in. thick and is welded at speeds above 200 ipm in a special vacuum chamber.

In an unusual application, described in Example 471, $\frac{5}{16}$-in.-thick duplex armor plate made of equal thicknesses of H11 tool steel and high-strength alloy steel AMS 6545 was welded without preheating or postheating.

The example that follows describes a salvage application in which both preheating and postheating were used.



Joint type	Circular corner, self-backing
Weld type	Square groove
Machine capacity	60 kv at 250 ma
Gun type	Pierce; triode(a)
Filament	Tantalum
Vacuum-chamber size	18 by 18 by 22 in.
Maximum vacuum	1.5 × 10⁻² torr
Fixtures	Holding jig; turntable
Preheat	350 F for ½ hr
Welding power	59 kv at 48 ma
Welding vacuum	6 × 10⁻² torr
Pumpdown time	30 to 45 sec
Beam spot size	About 0.030-in. diameter
Beam focal point	At surface
Power density	4 megawatts per square inch
Welding speed	53 ipm (10.4 rpm)
Revolutions per weld	3¼(b)
Total travel time	18.7 sec
Production rate	10 pieces per hour(c)
Postheat	Stress relieved at 1200 F for 1 hr

(a) Fixed operating position; vertically adjustable up to 19 in. (b) Cycle consisted of two revolutions at welding power and 1¼ revolutions on current downslope. (c) Does not include 3 hr for equipment setup and dismantling.

Fig. 42. Housing for an aircraft accessory control, showing original unbalanced flange design, which was likely to crack, and the improved ring-flange design, welding fixture, and improved joint design for medium-vacuum welding (Example 487)

Example 488. Salvage of a Damaged Tool Steel Die by Welding On a Replacement Flange (Fig. 43)

Electron beam welding was used to salvage a metal-powder compacting die made of H11 tool steel, the flange of which was damaged beyond use. The inside diameter of the die stem had been finished to a critical dimension, at considerable expense, making salvage desirable. The principal cost factor, however, was that a high-production compacting press was idle for the want of a die.

Figure 43 (top view) shows a cross section through the die, with the damaged flange machined off and a new flange press fitted and welded in place. The hardness of the H11 die was Rockwell C 60, and the new flange was of the same tool steel at the same hardness.

Salvage procedure consisted of the following operations:

1. Both parts were machined to dimensions (see Fig. 43) with a 0.002-in. diametral interference at the stem neck, and they were solvent cleaned. To reduce downtime, the joint on the stem was ground to dimensions at the same time that the flange was being machined, hardened and ground.
2. Press fitting was accomplished by heating the flange to 500 F (the stem being held at room temperature), and fitting the parts together on an arbor press. Flange and stem were mechanically held in position during cooling. Maximum surface mismatch allowed at the joint was 0.010 in.
3. The assembly was furnace preheated to 500 F (2 hr at temperature), and clamped in a three-jaw chuck that was mounted on a positioner in the vacuum chamber.
4. Welding vacuum was attained while the joint was positioned for precise beam location for making weld No. 1 (circumferential), in the horizontal-rolled pipe position.
5. The power settings, beam focus and welding speed were determined by trial before the repair operation was attempted (see table with Fig. 43). Because of the uncertain consequences of having the two welds intersect, they were kept at least 0.030 in. apart. Macrosections of welds on testing stock were examined to verify the settings.
6. After weld No. 1 was completed, the part was removed from the vacuum chamber and transferred to a furnace; it was heated to 500 F, held for 2 hr, and furnace cooled.
7. The weld was then examined visually and by magnetic-particle inspection.
8. Weld No. 2 (circular) was completed by the same procedure, except rotation was about the vertical axis and power settings were different (see table with Fig. 43).
9. The face and outside diameter of the flange were ground. No change in size or hardness of the internal die surface occurred during welding.

Salvage by electron beam welding saved an estimated $200 in die cost and about two days of downtime, as compared with making a new die. Other welding methods were considered impractical because (*a*) the heat input would have decreased the hardness of the die and possibly the dimensions of the bore, and (*b*) annealing and reheat treatment would have been necessary, with the consequent danger of further distortion.

The procedure was used to salvage six dies of similar tool steels and shapes.

Welding of Stainless Steels

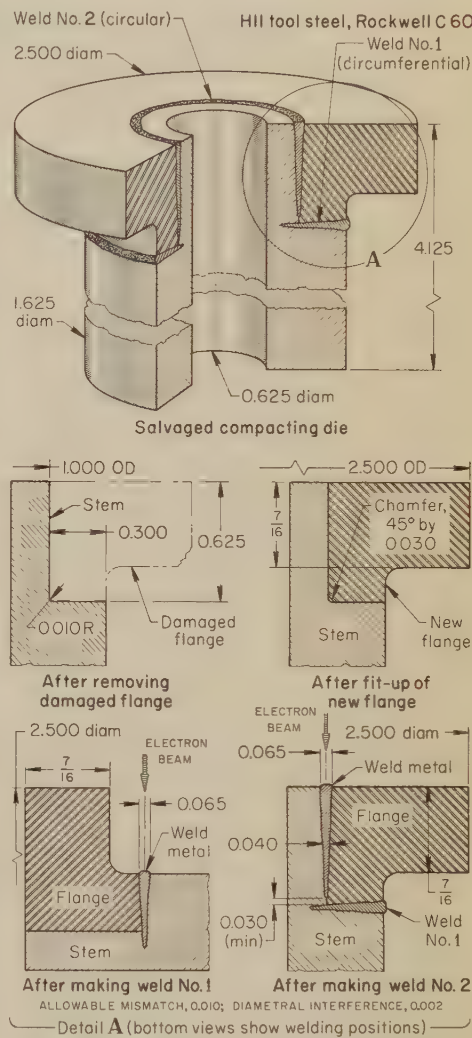
The properties and the welding metallurgy of the four groups of stainless steels are discussed in the article on Arc Welding of Stainless Steel, starting on page 245 of this volume.

Austenitic Stainless Steels. The high cooling rates typical of electron beam welding help to inhibit carbide precipitation, because of the short time during which the steel is in the sensitizing-temperature range.

Filler metal is used in welding joints that cannot be fitted together closely. The use of filler-metal preplacement is illustrated in Example 485, where a controlled-depth partial-penetration weld was required in a relatively open joint in type 304.

In attaching a rupture disk made of 0.002-in.-thick type 304 foil to a nozzle, severe burnback resulted when gas tungsten-arc welding was used. Electron beam welding solved the problem, as described in Example 476.

The welding of type 304 stainless steel to copper, to Hastelloy B, and to Inconel 600 is described in Examples 497, 499 and 501, respectively. An illustration of the range of heat control



Joint type	Circular and circumferential corner
Weld type	Square groove
Machine capacity	6 kw at 150 kv
Gun type	Fixed
Vacuum-chamber size	52 by 36 in. by 36 in. high
Maximum vacuum	10⁻⁶ torr
Fixtures	Rotatable positioner; three-jaw chuck
Preheat	500 F, for 2 hr at temperature, in a furnace
Welding power:	
Weld No. 1 (circumferential)	11 ma at 110 kv
Weld No. 2 (circular)	22 ma at 125 kv
Operating vacuum:	
During setup	2 × 10⁻⁴ torr
During welding	5 × 10⁻⁵ torr
Beam spot size	0.010 in.
Beam focal point	At surface
Welding speed:	
Weld No. 1 (circumferential)	30 ipm
Weld No. 2 (circular)	25 ipm
Postheat	500 F, for 2 hr at temperature

Welding Conditions for Salvaging

Joint type: Circumferential butt; rabbeted, self-backing	Welding power:
Weld type: Square groove	Tack welding: 90 kv at 1 ma
Machine capacity: 150 kv at 25 ma	Full welding: 110 kv at 5 ma
Gun type: Steigerwald; fixed	Welding vacuum: 4×10^{-5} torr
Maximum vacuum: 10^{-5} torr	Working distance: 6 in.
Vacuum-chamber size: 23 by 36 by 36 in.	Beam focal point: Sharp at pintle-tube surface
Fixtures: Special chuck(a); rotating positioner	Welding speed: 30 ipm (6.3 rpm)
	Welding time: 10 sec (automatic timer)

(a) Chuck consisted of a split aluminum ring designed to grip the critical area without distortion.

Fig. 44. Rocket-engine injector drive-housing assembly showing pintle-tube joint that was designed for salvage and reuse (Example 489)

possible with the electron beam is given in Example 631, in the article on Brazing of Stainless Steel.

Martensitic Stainless Steels. Although these steels can be electron beam welded in almost any heat treated condition, welding will produce a hardened, martensitic heat-affected zone. Hardness and susceptibility to cracking increase with increasing carbon content and cooling rate. Example 466 describes an application in which medium-vacuum electron beam welding replaced gas metal-arc welding.

Precipitation-hardening stainless steels can, in general, be electron beam welded to produce good mechanical properties in the joint. The semiaustenitic types, such as 17-7 PH and PH 14-8 Mo, can be welded as readily as the 18-8 types of austenitic stainless steel. The weld metal becomes austenitic during welding and remains austenitic during cooling. In the more martensitic types, such as 17-4 PH and 15-5 PH, the low carbon content precludes formation of hard martensite.

Some of the precipitation-hardening stainless steels have poor weldability because of their high phosphorus content. Steels 17-10 P and HNM are not usually electron beam welded.

An application that involved an unusually high degree of precision in joining 17-4 PH and 17-7 PH alloys is the flexure-bushing assembly described in Example 469. Another application involved a controlled-depth, partial-penetration weld in 17-4 PH alloy, as described in the following example.

Example 489. Electron Beam Welding of a 17-4 PH Part Designed for Salvage (Fig. 44)

Oxidizer pintle tubes, which formed part of the injector drive housings of lunar rocket engines, were designed for easy removal and salvage. A typical pintle tube, electron beam welded to its housing, is shown at the top in Fig. 44, and a cross-sectional detail of the joint in the initial assembly (as welded) is shown just below, at the right. Removal of the pintle tube was accomplished by machining away a short section of the tube at the weld. Salvage required fitting and welding on a new extension piece, which was machined to size, as shown in Fig. 44.

Reasons for this type of design were:

1 Pintle-tube alignment was crucial for optimum, smooth engine performance, and upon initial assembly, it was impossible to predict engine operating conditions and to weld the tubes for best alignment.
2 The precision-made housings cost approximately $10,000 each and required a long lead time. Therefore, salvage and reuse were highly desirable.

Electron beam welding was selected for both the initial and salvage welding operations because, in addition to providing the required mechanical properties, the low heat input minimized weld shrinkage and part distortion. Only the salvage operation is shown in Fig. 44 and dealt with in the accompanying table.

Neither preheating nor postheating was used in the salvage procedure. Both members of the joint were made of 17-4 PH stainless steel, solution heat treated and aged before assembly. No further heat treatment was permitted because close dimensional control would be lost.

The salvage welding, as indicated in the table with Fig. 44, required no special techniques. A used pintle tube was removed from its housing. The new extension piece was machined with a diametral clearance of 0.000 to 0.002 in. max, for fitting by hand. Parts were ultrasonically cleaned immediately after machining and wiped with acetone immediately before assembly.

A two-piece aluminum chuck was designed to hold the tube without affecting critical dimensions. The part was rotated, axis horizontal, under a fixed gun, without the use of beam oscillation. Four tack welds were made at 90° intervals. The welding cycle was automatically timed for one revolution plus a short overlap, automatic downslope being used to taper the power at the overlap. After machining excess material from the added section, the pintle tube was ready for reuse.

Welding of Heat-Resisting Alloys

Because of the marked differences in composition and weldability among heat-resisting alloys (nickel-base, iron-base, and cobalt-base), generalizations concerning electron beam welding of these alloys are not useful. Notes and references to examples follow.

Solid-Solution Nickel-Base Alloys. Hastelloy N, Hastelloy X and Inconel 625 are readily electron beam welded. In Example 499, Hastelloy B was welded to type 304 stainless steel. Inconel 600 was welded to itself and to type 304 stainless steel in Example 501.

Precipitation-hardenable nickel-base alloys that are rated good in weldability by the electron beam process include Inconel 700, alloy 718, Inconel X-750 and René 41. Alloy 718 can be welded in either the annealed or the aged condition. Inconel X-750 should be welded in the annealed condition, and René 41 should be welded in the solution-treated condition.

Alloys of this group that have fair weldability include casting alloys 713C and GMR-235 and wrought Udimet 700 and Waspaloy.

In Example 481, solution-treated René 41 was welded and then aged for 16 hr at 1400 F; selection of welding conditions for sound welds was important in this example, which involved two-tier welding at a separation of ½ in. In Example 465, a GMR-235 alloy casting was welded to case-hardened 8620 alloy steel.

Iron-Nickel-Chromium-Base Alloys. This group of alloys is also known as

the iron-base heat-resisting alloys. The most readily welded alloy of this group, using electron beam welding, is 19-9 DL, which has excellent weldability and on which the best results are obtained when preheating is used. Alloy N-155 has good weldability, and alloys 16-25-6 and A-286 are rated fair. Alloy A-286 is usually welded in the solution-treated condition; hot cracking may result if welding is done in the aged condition.

Cobalt-Base Alloys. HS-21 has good weldability in unrestrained joints (generally poor in restrained joints). Cast alloy HS-31 (X-40) has fair-to-good weldability, and alloy S-816 has fair weldability. Example 477 describes the successful electron beam welding of HS-25 castings when suitable procedures and precautions were used.

Welding of Refractory Metals

Electron beam welding is used for joining the refractory metals (tungsten, molybdenum, columbium, tantalum and their alloys), all of which have melting temperatures above 4000 F. The chief problem in welding these metals is embrittlement, caused by contamination. The electron beam process is especially well suited for welding refractory metals, because the vacuum prevents contamination.

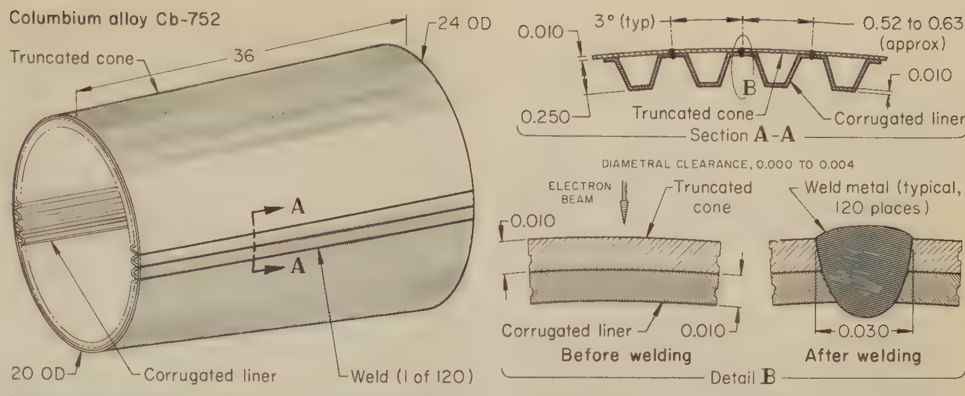
The main disadvantages of electron beam welding for joining the refractory metals are: (*a*) high welding speeds are not desirable in metals susceptible to thermal shock, (*b*) significant amounts of alloying elements that have high vapor pressures may be lost, and (*c*) some assemblies may require long times in the vacuum chamber, or forced cooling with inert gas to avoid atmospheric contamination.

Tungsten is the most difficult of the refractory metals to weld because of its high melting point (6170 F), sensitivity to thermal shock, and the room-temperature brittleness of the welds and of the heat-affected zone. Good and fair welding results have been reported for W-25Re and W-25Re-30Mo alloys, respectively.

Best results are obtained when assemblies are fixtured with the joint under compression during welding. Fixtures are often released after welding, to permit the weld to cool without restraint; if the weld is restrained during cooling, cracking is likely to occur. Preheating in the range of 1300 to 1400 F and postweld stress relieving at 1800 to 1900 F help to reduce stresses. Somewhat wider welds and lower welding speeds than are used for other refractory metals are desirable. Beam oscillation and pulsing are helpful. A 60-hertz deflection with an amplitude of 0.10 in. minimizes grain growth.

Molybdenum is almost as difficult to weld as tungsten. The cast weld structure is extremely brittle. Partly because of its lower melting point (4730 F), molybdenum has better thermal shock resistance than tungsten; thus, narrower welds and higher welding speeds can be used. The resulting lower heat input helps to reduce grain growth and intergranular segregation.

Preheating to about 400 F or higher is used with postweld stress relief at 1600



Joint and weld types	Lap; melt-through	Welding vacuum	10^{-5} torr
Machine capacity	60 kv at 500 ma	Beam focal point	At work surface
Gun type	Pierce; fixed	Working distance	3 in.
Maximum vacuum	10^{-7} torr	Welding speed	50 ipm
Vacuum-chamber size	112 by 50 by 62 in.	Number of passes	One
Fixtures	Semiautomatic indexing tool; traveling carriage	Preheat	None
Welding power	25 kv at 28 ma	Postweld heat treatment	Stress relieve at 2150 F for 90 min in an inert atmosphere

Fig. 45. Truncated cone and corrugated liner (members of a missile-body component) that were joined by electron beam melt-through welding, under conditions in table (Example 490)

to 1800 F. Beam oscillation is used to overcome undercut and surface roughness, which commonly occur.

Several molybdenum alloys have been electron beam welded, notably Mo-0.5Ti and TZM alloy (Mo-0.5Ti-0.08Zr-0.02W). Typical conditions used in butt welding 0.050 to 0.100-in.-thick Mo-0.5Ti are:

Preheat	600 F
Welding power	135 kv at 10 ma
Welding speed	27 ipm
Beam oscillation	60 hertz with 0.005-in. transverse deflection
Weld depth-to-width ratio	4
Heat-affected-zone depth-to-width ratio	2.2
Weld-zone grain size	ASTM No. 6

Columbium, which melts at 4474 F, is easier to weld than molybdenum or tungsten. Gas tungsten-arc welding is often used, but electron beam welding provides better protection, narrower welds, and lower heat input. Preheating is not necessary, but postweld vacuum stress relief is used to restore ductility and toughness, especially in the columbium alloys.

Unalloyed columbium is easily electron beam welded, but has relatively low strength. More alloys have been developed, mainly for higher strength, than for the other refractory metals. Alloying usually reduces weldability, but most weld joints in alloys retain about 75% efficiency, and good structural properties can be obtained for service temperatures in the range of about 2000 to 3000 F, depending on the alloy. Chill tooling is often used, but copper, nickel and stainless steel should be avoided, to prevent contamination of the weld metal.

In the example that follows, good weld ductility was required in joining a missile cone to a missile liner, because of differential thermal stresses in service and the need to prevent distortion.

Example 490. Electron Beam Melt-Through Welding of Columbium Alloy Cb-752 (Fig. 45)

Both members of a missile-body component (a truncated cone and a corrugated liner) were made of columbium alloy Cb-752 (0.03 C max, 0.0020 H max, 0.04 O max, 0.01 N max, 2.0 to 3.0 Zr, 9.0 to 11.0 W, rem Cb). As shown in Fig. 45, the liner corrugations ran from the top of the cone to the base, parallel to the sides, making 120 equally spaced contacts with the inside surface of the outer shell. The assembly required 120 longitudinal welds about 0.52 to 0.63 in. apart (3° of arc) to join the two components at the contact surfaces. There were no weld grooves; each component was formed from a continuous sheet.

Maintaining the structural integrity of the assembly for service requirements involving high-temperature cycling was the major fabricating objective.

Electron beam welding under relatively high vacuum was selected for this application because the absence of an atmosphere had been found to be more effective in avoiding embrittlement than the use of an inert gas. In addition, the smaller welds and higher welding speeds obtained minimized distortion and structural changes due to the welding heat. Power was easily adjusted to achieve a continuous weld that fully penetrated both sheets in a single pass, using the keyhole technique.

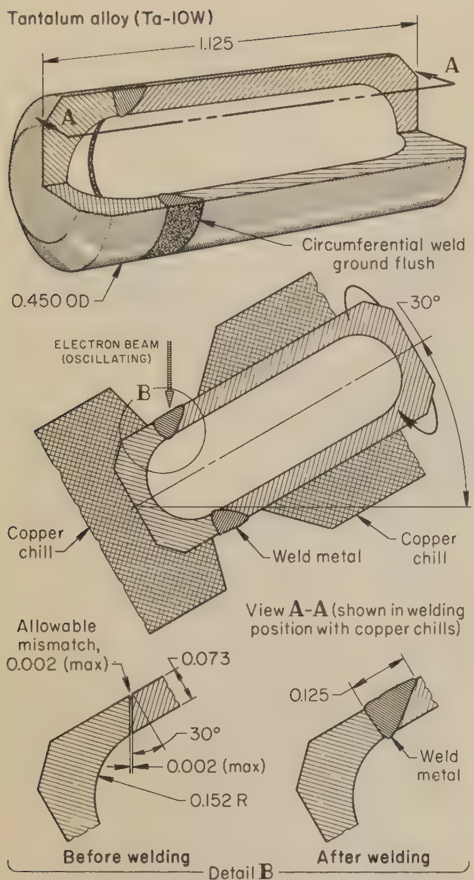
The alloy was in the annealed condition before welding and required stress-relief heat treatment after welding. Preweld cleaning consisted of chemical etching and wiping with alcohol just before welding. All joint surfaces were machined or drawfiled. White gloves were worn for all handling of parts between final cleaning and welding.

The two components were assembled in a semiautomatic indexing fixture in which the hold-down bars were changed manually after completion of each longitudinal weld. For each weld, therefore, a separate vacuum pumpdown was required. As shown in section A-A of Fig. 45, clearance tolerances at the surfaces to be welded were held as close to intimate contact as was feasible. Each end of the cone was machine trimmed after welding.

Details of the equipment and machine settings used for this operation are summarized in the table with Fig. 45.

To determine the effectiveness of the welding procedure, the following tests were made. Weld surfaces were examined by liquid-penetrant inspection. Radiographic inspection was used to detect cracks and voids. Weld joints, with weld reinforcement removed, were bent over an arc of 105°, using an 0.080-in.-diam mandrel. Both root and face bends were required to show no cracks when examined visually at 10×.

Tantalum is the most easily weldable of the four refractory metals. Because of its high melting point (5425 F) and good thermal conductivity, thicknesses of 0.060 in. or more must be rapidly



Joint type	Circumferential butt
Weld type	30° slant groove
Machine capacity	150 kv at 40 ma
Gun type	Steigerwald triode; fixed
Filament	Tungsten hot wire
Vacuum-chamber size	23 by 36 by 23 in.
Maximum vacuum	10^{-5} torr
Fixtures	Three-jaw chuck; spindle; copper chills
Welding vacuum	10^{-4} to 5×10^{-5} torr
Pumpdown time	5 min
Welding power	120 kv at 10 ma
Preheat power	120 kv at 5.5 ma
Number of passes	Four (three preheating, one welding)

Working distance	6 in.
Welding speed	45 ipm (31.8 rpm)
Parts per chamber load	One

Fig. 46. Tantalum alloy capsule that was full-penetration welded for high creep-rupture joint strength (Example 491)

heated to high temperatures for welding. Copper chills are used to avoid distortion and weld sagging and to shorten the time the assembly has to remain in the vacuum chamber, thus limiting grain growth.

Weldability of tantalum alloys containing other refractory elements is somewhat lower than that of unalloyed tantalum. Because of high vapor pressure, alloys containing vanadium are better welded by the gas tungsten-arc process. One of the most common alloys is Ta-10W, which was welded in the following example.

Example 491. Full-Penetration Welding of Ta-10W for High Creep-Rupture Strength (Fig. 46)

Electron beam welding was selected for making the closure weld in the capsule shown in Fig. 46. Requirements called for a full weld with complete joint penetration, a smooth, spatter-free interior, and high creep-rupture strength. The Ta-10W joints could have been welded by the gas tungsten-arc process, in an inert atmosphere in a welding chamber, but joint properties probably would have been lower. Also, the gas tungsten-arc process, with larger weld zones, greater heat input, and a wider heat-affected zone, was likely to increase the extent of grain growth, thereby reducing creep-rupture strength. Another factor favoring the selection of electron beam welding was that welding under vacuum minimized gaseous contamination, to which the alloy was highly susceptible.

Successful production of the capsules depended on a consistently reproducible welding procedure, as evidenced by consistency of results in a series of qualification tests. Although such a procedure was developed, special precautions were needed to control root-face "suck-back", internal spatter, and weld-face underfill. For high service reliability, each welded capsule was inspected by liquid-penetrant and radiographic methods; in addition, one capsule in ten was tested destructively for strength and was examined metallurgically. Details of the welding procedure and sequence of operations are described below.

The 30°-slant butt joint shown in detail B of Fig. 46 was designed for self-aligning, accurate fit-up and to facilitate radiographic examination. After careful machining to avoid broken joint edges, the surfaces were cleaned by wiping with acetone. Dye marks were placed on one side of the joint to aid in aligning the beam on the joint, because the close fit-up made it difficult to distinguish the joint from machining marks. The dye, a film only a few angstroms thick, vaporized on heating, without contaminating the weld.

The parts were fixed in copper chill blocks and assembled by chucking and aligning to tolerance in a spindle set at a 30° angle, as shown in Fig. 46, view A-A. During vacuum pumpdown, beam alignment was set within 0.002-in. runout by sighting a low-power beam with a 20-power optical attachment.

Copper chills were used to prevent distortion and to shorten cooling time under vacuum, thus limiting grain growth. Adequate cooling time under vacuum was necessary because the alloy was susceptible to atmospheric contamination at elevated temperatures. The relatively low heating and cooling rate of the alloy, together with the absence of convection cooling in the chamber, would have considerably delayed vacuum release if chills had not been used. Because the tantalum alloy was not hardenable by heat treatment, hardenability, as such, was not a factor in preheating or chilling.

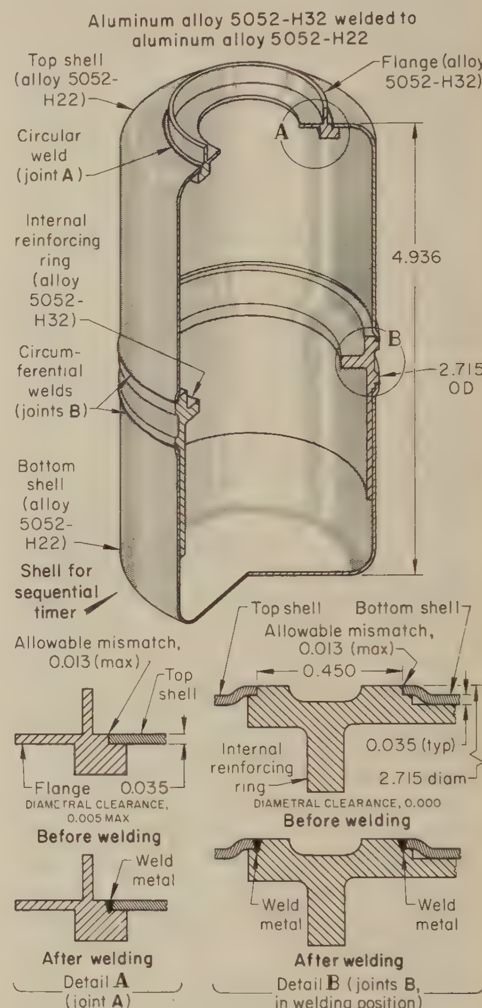
Both preheating and beam oscillation were found to be necessary to obtain the required weld shape on the inner and outer weld surfaces, and to reduce internal spatter. One of the problems in welding this alloy, the tendency of the weld to draw back from the root into the joint, due to the very high surface tension of the molten metal, aided possibly by an internal pressure buildup, and another problem, filling the hole that was created on starting the weld, were overcome by preheating and beam oscillation. Although both procedures added heat, the travel speed (45 in. per minute) kept welding heat input at 1.6 kilojoules per inch, the effect of which was reduced by the chills.

Preheating was accomplished by making three passes with the electron beam at low power (partially defocused). After the third pass, power was increased for welding, which was done in a single pass. Both preheating and welding were done with the beam oscillating linearly in the direction of the weld. Welding conditions are given in the table accompanying Fig. 46.

The welding problems mentioned above were reduced to an acceptable level, but not eliminated. Because quality assurance, rather than high production rate, was the objective, only one capsule was welded per pumpdown. Sampling for destructive testing was relatively high, at 10%, indicating the application to be too critical for reliance on nondestructive testing alone.

Welding of Aluminum Alloys

Single-pass full-penetration welds with depth-to-width ratios of more than 20 to 1 have been made in 6-in.-thick aluminum alloy plates.



Joint type, joint A	Circular butt; rabbeted, self-backing
Joint type, joints B	Circumferential butt; rabbeted, self-backing
Weld type (all joints)	Square groove
Machine capacity	150 kv at 40 ma
Gun type	Steigerwald triode; fixed
Vacuum-chamber size	36 by 23 by 30 in.
Maximum vacuum	10^{-5} torr (approx)
Fixtures	Universal chuck; lathe-type spindle; carriage with x-y drive
Filler metal	None
Welding power:	
Joint A, tack welding	110 kv at 2.5 ma
Joint A, full welding	130 kv at 5 ma
Joints B, full welding	120 kv at 5.5 ma
Welding vacuum	10^{-4} torr, approx (all welds)
Beam focal point	Sharp at surface (all welds)
Beam oscillation	0.010-in. diameter at 1000 hertz(a)
Welding speed:	
Joint A	77 ipm (14 rpm)
Joints B	119 ipm (14 rpm)
Working distance	7.5 in. (all welds)(b)
Production rate	4 parts per hour

(a) Circular deflection. (b) Measured from the top of the chamber to the workpiece.

Fig. 47. Sectioned view of the shell of a sequential timer, and details of the circular and circumferential joints welded by the electron beam process (Example 492)

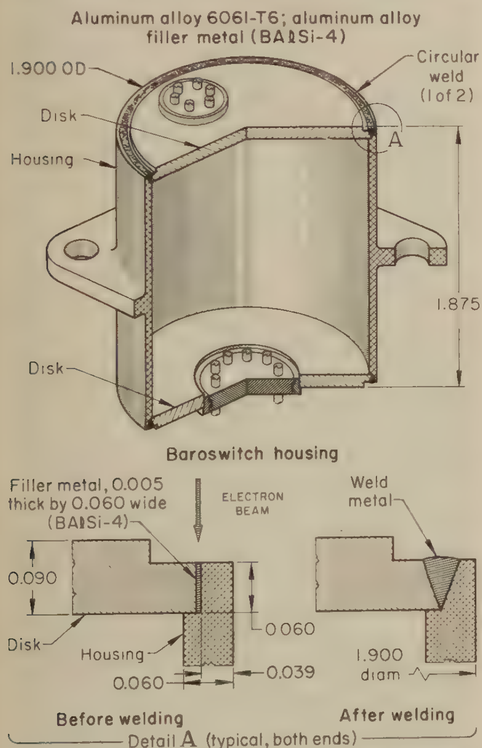
The low heat input, narrow heat-affected zone, and short heat cycle result in minimum decrease in mechanical properties, especially in assemblies of some of the heat treatable alloys.

Non-Heat-Treatable Alloys. The mechanical properties of electron beam welds in the non-heat-treatable alloys (1*xxx*, 3*xxx*, 5*xxx* series) are virtually the same as those obtained by gas tungsten-arc welding. If the alloy is in a strain-hardened condition, the weld properties closely approach the annealed properties of the base metal.

Obtaining maximum joint strength is not the principal objective in all applications. In welding nuclear fuel elements, as in Example 474, obtaining a tight closure and a narrow full-penetration weld were the objectives. In the application described in the example that follows — welding a thin-wall enclosure made of alloy 5052 in the strain-hardened condition — freedom from distortion was a critical factor.

Example 492. Welding a Thin-Wall Aluminum Alloy 5052 Assembly (Fig. 47)

Figure 47 shows the structural details of a shell for a sequential timer. The circular joint and the two circumferential joints



Joint type	Circular corner; rabbeted, self-backing
Weld type	Square groove
Machine capacity	150 kv at 40 ma
Gun type	Steigerwald triode; fixed
Vacuum-chamber size	36 by 23 by 30 in.
Maximum vacuum	10^{-5} torr
Fixtures	Universal chuck, turntable
Filler metal	0.005-in.-thick foil of BAlSi-4
Welding power	110 kv at 4 ma
Welding vacuum	10^{-4} torr, or less
Beam focal point	Sharp at surface
Beam oscillation	0.010-in. diameter at 1000 hertz(a)
Welding speed	101.2 ipm (18 rpm)
Working distance	8 in.(b)
Production rate	5 parts per hour

Fig. 48. Baroswitch housing that was electron beam welded with preplaced filler metal, to avoid cracking (Example 493)

used to fabricate the assembly were electron beam welded because small, accurate, partial-penetration welds were required, to minimize distortion and yet provide hermetic seals.

The non-heat-treatable 5052 base metal was strain hardened and partially annealed (H22), or strain hardened and stabilized at low temperature (H32), for the various components, as shown in Fig. 47. Preheating and postheating were neither desirable nor necessary. Unlike some heat treatable alloys (see Example 475), alloy 5052 did not require a filler-metal addition to prevent cracking.

After components were formed and machined, they were cleaned and degreased. Just before assembly for welding, components were brushed clean of oxide film with a stainless steel wire or a fiber glass brush, and wiped clean of dust with a solvent. No fingerprints were permitted on cleaned surfaces.

Assembly and welding of the unit were done in two stages, each stage requiring a separate pumpdown. First, the top flange and top shell were assembled by means of an internal fixture mounted on a turntable in the vacuum chamber. An external fixture lightly held the shell in position for tack welding. The chamber was evacuated and the joint (joint A in Fig. 47) was optically aligned (using a 20-power telescope) under the fixed beam, with runout not exceeding 0.001 in. The telescope was equipped with a reticle graduated in thousandths of an inch. With the assembly rotating about its vertical axis, four tack welds were made, with circular beam oscillation, at 90° intervals. A preset weld timer controlled tack-weld length.

Full welding of each joint was done by starting rotation and holding the "on" button for one complete revolution, and then pressing the "off" button. Automatic current downslope tapered beam power to zero over a very short distance of approximately 5° of revolution. Detail A in Fig. 47 shows joint A before and after welding, and the accompanying table gives the machine settings used for all welding operations.

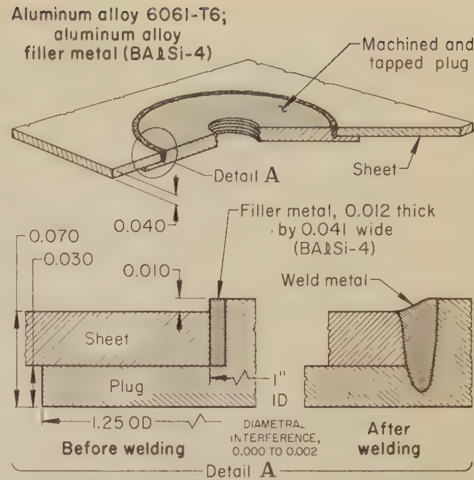
Vacuum was released, the subassembly was removed, and the remaining components were assembled. The assembly was chucked (axis horizontal) between the headstock and tailstock of a lathe-type spindle, with sufficient pressure to eliminate the need for tack welding. The two circumferential joints (joints B in Fig. 47) were welded, with beam oscillation, in one pumpdown. The first joint was optically aligned and welded, and then the second joint was moved into alignment by the motor-driven carriage that supported the entire fixtured assembly. Details of joints B, before and after welding, are shown in detail B in Fig. 47; welding conditions are included in the accompanying table.

Completed enclosures had to meet helium leak-rate tests with rates not exceeding 10^{-7} cu cm helium per second at 1 atm pressure. Periodically, three enclosures were selected for destructive testing, which consisted of tension testing and macroscopic examination for weld soundness. Similar tests were also made on a regular sampling basis of one part out of twenty.

Heat treatable alloys of series 2*xxx*, 6*xxx* and 7*xxx* are crack sensitive to varying degrees when welded. The condition of the zone immediately adjacent to the weld is critical in determining weldability.

The 6*xxx* alloys are only slightly affected by the heat cycles of electron beam welding. Alloys 2219, 7039 and 7005 appear to be the least affected of the alloys of their respective series. The techniques used to prevent cracking in electron beam welding the heat treatable aluminum alloys are:

1 Special care in preweld cleaning to avoid porosity and oxide inclusions in the weld metal



Joint type	Circular butt; rabbeted, self-backing

Fig. 49. Repair of a partly processed sheet metal part, showing a replacement plug welded in place, using preplaced filler-metal foil (Example 494)

2 Prestressing joints in compression by using interference fits when possible

3 Use of a ductile filler metal, usually in the form of a thin strip preplaced in the joint, which will yield under shrinkage stresses and fill joint openings

4 Selection of beam power, beam spot size, and welding speed to create as narrow welds as practical during short welding heat cycles, thus avoiding excessive grain-boundary melting

5 Use of postweld heat treatment to restore the strength and ductility of the weld and heat-affected zones

6 Other techniques include designing or locating joints to be free of externally imposed restraints, reinforcing of joint areas and, when possible, welding in the solution-treated condition, with postweld aging.

In the highly critical welding of loaded fuze assemblies made of alloy 6061-T6 (Example 475), a brazing sheet giving good ductility was used as filler metal. In the next example, foil filler metal was used to prevent cracking of an alloy 6061-T6 instrument housing.

Example 493. Use of Filler Metal To Prevent Cracking in Welding a Heat Treatable Aluminum Alloy (Fig. 48)

The baroswitch housing shown in Fig. 48, which supported and protected an internal pressure-sensing and switching mechanism, was made of alloy 6061-T6. This material, like other heat treatable aluminum alloys, was crack-sensitive when welded to itself, but no cracking could be tolerated in this application. The cracking problem was solved by use of a suitable filler metal in the form of 0.005-in.-thick foil preplaced in the joints.

The filler metal selected was BAlSi-4, an aluminum alloy containing about 12% silicon. The filler-metal foil was cut into

Fig. 50. Four types of joints used in fabricating an electronic-detector package (Example 495)

strips 0.060 in. wide, deburred by drawing over the edge of a sharp knife, cleaned with solvent, and wiped dry just before use. The strips were hand fitted into the joint, which had previously been machined to allow about 0.001-in. clearance after fitting. To allow for machining variations, filler-metal thicknesses of 0.004 and 0.006 in. were also available.

Using the BAlSi-4 filler metal, the desired weld-metal composition and properties were obtained.

In this application, the procedures for preweld cleaning, assembly, fixturing, beam alignment and welding were essentially the same as those described in Example 475. Tack welding was not used; instead the weld was made at a much higher speed, reducing the heat input considerably (0.26, as compared to 0.61 and 0.75, kilojoules per inch). High-speed welding also helped to prevent cracking.

Welding conditions are given in the table accompanying Fig. 48.

Repair welding entails the same procedures and requires the same care as assembly welding, although the length of repair welds is usually shorter. Repair of 6061-T6 sheet by welding a replacement plug of the same material is described in the following example.

Example 494. Use of a Plug and Preplaced Filler Metal To Repair Small Defects in Aluminum Alloy Sheet (Fig. 49)

Improperly drilled or tapped holes in partly processed precision components were repaired by cutting out the defective region and welding in a small plug, using the electron beam process. Care was required to avoid cracking and distortion, because of high joint restraint (the plug was press fitted). Figure 49 shows a typical repair made in alloy 6061-T6 sheet. In this instance, repair was complicated because a small tapped hole was to be located within the repair area, and tapping required a plug of the 6061-T6 alloy, for hardness.

A high-silicon filler metal was used, to avoid cracking due to hot shortness. If a plug of softer material, such as aluminum alloy 1100, could have been used, added filler metal would not have been required. A plug made entirely of a high-silicon filler metal, such as 4043 or 4047, also would have been satisfactory, but these materials were not readily available, except in wire and sheet forms. Filler metal used in this repair was a 0.012-in.-thick shim of BAlSi-4 brazing filler metal (4047 alloy).

Preparation for the repair consisted of cutting a 1-in.-diam hole to remove the defective area and machining a plug with a 0.002-in. max interference (Fig. 49). The weld area was carefully cleaned to remove all traces of oil and oxide. The filler metal was wire brushed with stainless steel bristles, cut to size, and fitted tightly around the plug. The plug was then inserted in the hole by means of a press fit.

After mounting the workpiece on a variable-speed turntable in the vacuum chamber, with copper chills around the plug, and aligning the beam on the joint, the chamber was evacuated. Four tack welds, each 0.20 in. long, were made to anchor the filler metal and hold the plug in alignment during welding. The tack welds were allowed to cool, and welding was done in a single pass, using automatic power downslope for approximately ⅜ in. after passing the starting point. The crossover from weld stop to start had been the most difficult area in controlling cracking, porosity and incomplete fusion when the welding schedule was being developed, prior to the actual repair. Beam oscillation and the conditions that produced satisfactory welds are summarized in the table with Fig. 49.

The view at the top in Fig. 49 shows the completed repair, with the plug machined flush on the outer surface, and the newly tapped hole. The inner projection of the plug was machined flush only when necessary for clearance.

Welding practice in joining cast aluminum alloys to themselves or to wrought alloys is generally the same as for joining wrought alloys. In Example 480, a difficult-access repair in a part fabricated from the heat treatable casting alloy 356 was made by welding a sleeve within an oversize bore.

Alloy 2024, one of the more crack-sensitive alloys of the 2xxx series, is almost never welded. In the manufacture of aircraft pontoons made of stretch-formed 2024 alloy, for instance, welding is prohibited before or after

forming. When fabricating conditions permit no alternative, however, special techniques can be used, as is described in Example 498.

In the example that follows, satisfactory seal welds were made without using filler metal.

Example 495. Electron Beam Welding of Aluminum Alloy 2024-T4 for Hermetic Sealing (Fig. 50)

Fabrication of a rush order for electronic-detector packages called for electron beam welding of four joints between components made of aluminum alloy 2024-T4. This alloy was used for the enclosures because the connector components were quickly available in the alloy. The chief objective in fabrication was to make a weld that would pass a helium leak test, rather than to develop the full strength properties.

Time was not available for development of the optimum procedure; machine settings were adopted as soon as results proved satisfactory. All welds were made using a high-voltage machine with a fixed gun of the triode type. The machine was rated at 150 kv at 40 ma. The vacuum chamber, 36 by 23 by 30 in. in size, was capable of a maximum vacuum of 5×10^{-5} torr. Fixtures included holding clamps, a travel carriage, and an eccentric circle generator. Machine settings for each weld are given in the table with Fig. 50, and the joints are shown in Fig. 50. Other factors affecting the procedure were as follows.

Joint A. Joining a pinch-off tube to the enclosure plate required a square-groove weld in a 1-in.-diam circular joint, as shown in the upper left of Fig. 50. The enclosure plate was recessed to a depth (0.090 in.) equal to the thickness of the pinch-off-tube flange with an interference on the diameter of 0.002 to 0.003 in. for a press fit.

During welding, the circular path of the joint was tracked by the beam, using a circle generator. This device consisted of a welding table driven in the horizontal plane by two eccentric drives so as to generate a circle by translation rather than by rotation. By selecting precalibrated settings on the control unit, any circle up to 2 in. in diameter could be accurately described by the table and any workpiece on it.

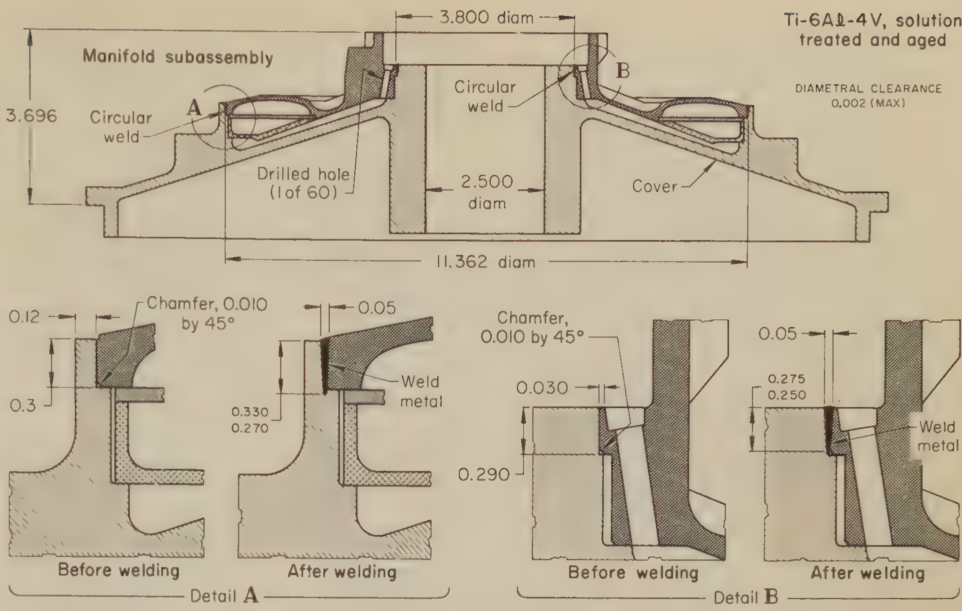
No difficulty was encountered in meeting leak-rate requirements using the conditions shown in the table with Fig. 50.

Joint B. From a welding point of view, the radio-frequency connector of the electronic-detector package differed from the pinch-off-tube component in these respects: (*a*) the flange was silver plated and was thinner (0.035 in.), (*b*) the flange diameter was smaller (0.687 in.), and (*c*) the flange contained a glass-to-metal seal, easily damaged by heat. Joint tracking was done by the circle generator.

Initially, welding was attempted by positioning the flange on the flat surface of the enclosure plate and fusing the flange edge to form a fillet weld. A satisfactory weld was obtained at a current of 8 ma, but the heat sometimes cracked the glass-to-metal seal. At lower currents, weld cracking occurred. By recessing the plate, using an interference of 0.0003 in. max on the diameter, it was possible, after a light press fit, to weld the joint at 6 ma without damaging the seal.

Joint C. Holes 0.395 to 0.397 in. in diameter were drilled in the 1-in.-thick enclosure plate during fabrication, to provide access for internal machining. The holes were sealed by welding in 0.40-in.-diam plugs that had been pressed in place. Depth of penetration was not critical for these welds, so long as they proved tight in leak testing. Partial-penetration welds only 0.150 in. deep proved satisfactory. There were no particular problems in meeting requirements when the circle generator was used together with the conditions shown in the table with Fig. 50.

Joint D. The cover plate of the rectangular electronic-detector package called for four welds to seal the unit hermetically. A separate vacuum pumpdown was required for each weld. Rectilinear motion was obtained by means of a track-guided carriage, which was part of the equipment. The most critical portions of these welds were at the package corners, where the beam entered and left the joint, resulting in weld intersection. Careful use of starting and runoff tabs was necessary to obtain leak-tight joints. Tabs were lightly tack welded, so that they could be broken off after welding and the rough spots filed smooth. Sometimes, repair welding was necessary. The use of a softer beam focus and a circular beam oscillation was found desirable. Welding conditions for joint D are listed in the table that accompanies Fig. 50.



Joint type ....Circular corner, self-aligning	Gun type ....Steigerwald triode; fixed
Weld type ....Square groove	Maximum vacuum ....10^{-5} torr
Machine capacity ....150 kv at 40 ma	Vacuum-chamber size ....23 by 36 by 36 in.

	Weld A	Weld B(a)
Welding power:		
Tack welding	110 kv at 4 ma	110 kv at 4 ma
Full welding	130 kv at 20 ma	130 kv at 16.9 ma
Working distance	6 in.	5¼ in.
Beam focal point	At work surface (all welds)	At work surface (all welds)
Beam oscillation(b)	0.043 in., at 1000 hertz	0.043 in., at 1000 hertz
Welding speed	61 ipm (1.7 rpm)	60 ipm (5 rpm)

(a) Holes near weld B were chilled with copper inserts and a copper ring that was fitted over the holes. (b) Oscillation was in a straight line (rectilinear), and tangential to joint circle.

Fig. 51. Manifold subassembly of a rocket-engine fuel injector, showing the two major joints welded by the electron beam process. Weld shown in detail B was especially critical because of proximity to drilled holes. (Example 496)

Welding of Copper and Copper Alloys

The electron beam welding of copper and its alloys is influenced by the same factors that affect the arc welding of these metals (see the article on Arc Welding of Copper and Copper Alloys, pages 337 to 357 in this volume). The high thermal conductivity of copper causes less difficulty in electron beam than in arc welding.

Molten metal may be expelled from the weld joint during electron beam welding of nondeoxidized coppers (especially alloy 110, ETP copper), causing spatter and uneven weld surfaces, but this can usually be remedied by the use of a cosmetic pass. The vacuum environment avoids possible hydrogen embrittlement; nevertheless, root voids and porosity still can occur.

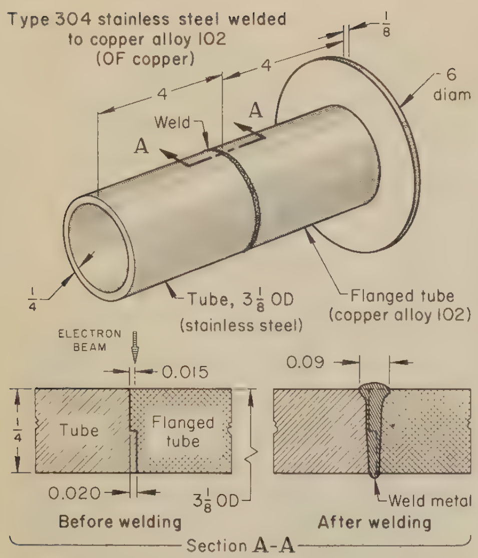
The presence of low-melting elements ordinarily makes the welding of free-machining copper alloys impractical, and the volatility of zinc prevents the welding of the brasses and other zinc-containing copper alloys. The remaining copper alloys shown in Table 1 on page 338 in "Arc Welding of Copper and Copper Alloys" can be electron beam welded without any unusual problems, except for alloy 175 (high-conductivity beryllium copper), for which the welding conditions must be controlled within a very narrow range to produce sound welds, and special safety precautions must be taken because of the toxicity of beryllium.

Applications. The electron beam welding of copper is described in Examples 482, 497 and 502 in this article.

Welding of Magnesium Alloys

Electron beam welding is used to a limited extent, chiefly for repair, on commercial wrought and cast magnesium alloys that contain less than 1% zinc. The relative suitability of alloys for electron beam welding is generally the same as for arc welding, as discussed in the article on Arc Welding of Magnesium Alloys (pages 358 to 365).

Special techniques and close control of operating variables are needed in order to prevent voids and porosity at the root of the weld, because of the high vapor pressure of magnesium, which has the lowest boiling point (2025 F) of any commonly welded metal. This difficulty is aggravated by the presence of zinc, which has a still lower boiling point (1663 F). It is ordi-



Joint type	Circumferential butt; double-rabbeted, self-aligning
Weld type	Square groove
Welding power	22 kv at 100 ma
Beam spot size	0.03-in. diameter
Beam focal point	At work surface
Working distance	1¾ in.
Welding speed	37 ipm
Welding vacuum	10^{-4} torr
Heat input	3.57 kilojoules per inch
Number of passes	One(a)

(a) Plus a cosmetic pass, which was applied later by manual adjustment of beam power

Fig. 52. Welding of a copper alloy 102 flanged tube to a type 304 stainless steel tube (Example 497)

narily impractical to electron beam weld magnesium alloys that contain more than 1% zinc.

Circular oscillation of the beam or the use of a slightly defocused beam is helpful in obtaining sound welds. The most satisfactory technique involves (*a*) the use of integral or tightly fitted backing of the same alloy and (*b*) close control of welding conditions to values that trial welds have shown will either minimize porosity and voids or localize them in an area where they can be machined away later or where they can be tolerated.

Applications. Alloys that have been electron beam welded with good results include casting alloy AZ91C-T6 and wrought alloy AZ80A-T5. Example 479 describes an application in which alloy AZ91C was welded for repair of fatigue cracks in a difficult location.

Welding of Titanium Alloys

All of the commercial alloys of titanium that can be joined by arc welding can also be joined by electron beam welding. Their relative weldability and response to heat cycling in electron beam welding are generally the same as in arc welding, which is discussed in the article on pages 375 to 382 in this volume.

Applicability. The vacuum environment of electron beam welding prevents exposure to the atmospheric contaminants that cause embrittlement of titanium alloys, whereas arc welding processes must use elaborate and costly shielding methods to accomplish this.

Cost studies on welding of Ti-7Al-2Cb-1Ta have shown that direct labor costs for electron beam welding are less than for arc welding, for sections more than 1 in. thick, if a suitably large vacuum chamber is available. A circumferential weld made in a 7-ft-diam, 2⅛-in.-wall cylinder for a deep-submergence vessel took 168 hr for gas metal-arc welding, and approximately 35 min for electron beam welding, including tack welding, penetration welding, repair welding, and a cosmetic pass, but not pumpdown and setup. The detailed cost comparison between electron beam welding and gas metal-arc welding in the Appendix to this article shows little difference for joining ¼-in. thicknesses of Ti-6Al-4V, but a substantial advantage in cost for electron beam welding of 1-in. plate.

Techniques. Filler metal is not ordinarily used, and the work is not preheated. Tack welding, contrary to experience in gas tungsten-arc welding, presents no difficulties in electron beam welding. For optimum results, welding is done in a high vacuum, but medium-vacuum welding is satisfactory in many applications.

Alloy Ti-6Al-4V, the alloy most frequently used in assemblies to be welded, can be electron beam welded in either the annealed or the solution-treated-and-aged condition. For weldments that will be used at elevated temperatures, a preferred process sequence is anneal, weld, solution treat and age. For other service conditions, a process sequence of solution treat, age, and weld gives almost the same strength properties and only slightly lower fracture toughness. This process sequence was used in the application described in the following example.

Example 496. Welding a Heat Treated Ti-6Al-4V Assembly for Close Dimensional Control (Fig. 51)

Design of the complex fuel-injection system of a lunar-module landing engine was based on the use of electron beam welding for joining components of various subassemblies. Electron beam welds provided strength, freedom from distortion, and freedom from burn-through of thin walls.

A typical subassembly was the manifold shown in cross section at the top in Fig. 51. It consisted of two conically shaped parts and was assembled by fitting the upper chambered portion into the solid lower portion, which served as the cover of the combustion chamber. Circular welds A and B sealed the subassembly, providing a conical space between the parts for smooth fuel distribution and cooling of the cover. Other details of fuel and oxygen flow, as well as other welds, have been omitted for simplicity. Enlarged details A and B in Fig. 51 show that the weld at B was the more critical, because of its proximity to 60 drilled holes (0.030 in. from the centerline of the weld joint).

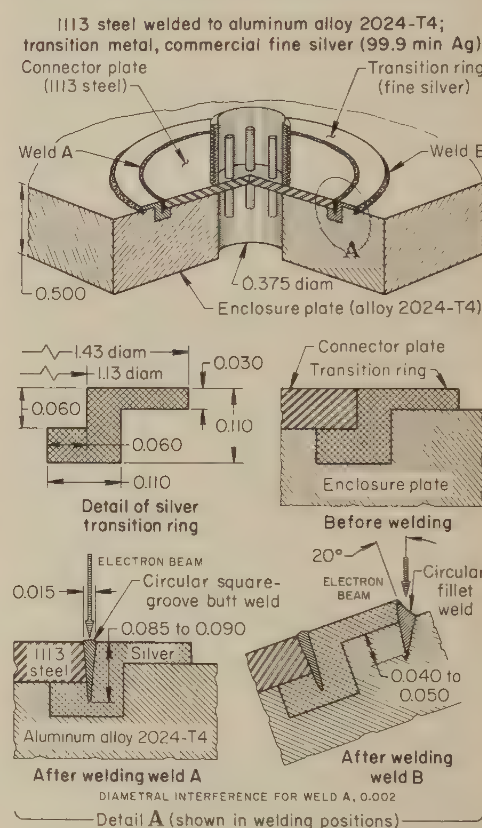
Material for this application was alloy Ti-6Al-4V, solution treated and aged before welding. Postweld heat treatment was not possible because it would have caused excessive distortion, even though several areas were finish machined after welding.

The joints were machined with a 0.002-in. maximum diametral clearance. Also, to facilitate fit, the corner edge of the male part was chamfered, as shown in Fig. 51.

Before assembly, joint surfaces were cleaned by acid pickling and ultrasonic cleaning. Just before welding, the joints were wiped with acetone.

After assembly, the workpiece was clamped in a fixture (not shown) mounted on a turntable in the vacuum chamber. The beam was aligned for weld B while the chamber was being evacuated. Four tack welds were placed at 90° intervals, between holes. The part was moved sidewise, the beam was aligned for weld A, and eight equally spaced tack welds were deposited. Weld A was then completed in one revolution, using beam oscillation and power downslope control. Machine settings and other conditions for these operations are given in the table with Fig. 51.

For the final weld at B, the vacuum was released and the beam realigned. For making this difficult weld, part of the clamping fixture was removed to facilitate the positioning of copper inserts in the holes drilled close to the joint, and to fit a copper ring over the inserts. This precaution was necessary to prevent burn-through in areas where the holes were within 0.030 in. of the joint. A gear change was also required in the turntable drive to maintain a high welding speed on the smaller circle. After pumpdown, the weld was completed in a single pass, using the same oscillation and slope techniques that had been used



Joint type, weld A	Circular butt; rabbeted, self-backing

Working distance, heat shield to work	10 in.
Welding speed:	
Weld A	35 ipm (10 rpm)
Weld B	45 ipm (10 rpm)
Beam oscillation	None
Number of passes	One, plus 60° downslope

Fig. 53. Electrical connector plate mounted on the enclosure plate of an electronic-detector package, showing use of a silver transition ring to make a hermetic-seal weld between resulfurized steel and an aluminum alloy (Example 498)

for weld A. However, as shown in the table with Fig. 51, other machine settings were different. Despite the copper chills, it was necessary to use lower amperage for better heat control. Weld penetration was also reduced, as indicated in Fig. 51.

Joining of Dissimilar Metals

The joining of dissimilar metals is an important application of electron beam welding. Many combinations that are difficult to weld or unweldable by other processes can be welded by the electron beam process.*

Indirect Joining. Combinations that cannot be joined directly by electron beam welding can usually be welded by this process when a transition piece or a preplaced filler-metal shim of a metal that is compatible with both work metals is used. This technique was used in Example 498.

Examples of practice in this article that describe direct electron beam welding of dissimilar metals include:

Example	Work metal A	Work metal B
465	8620 steel	Nickel-base GMR-235
478	Invar (64Fe-36Ni)	72Mn-18Cu-10Ni
483	4130 steel	Monel K-500
501	Type 304 stainless	Inconel 600

In each of these examples, some aspects of the welding required special attention because of problems posed by the dissimilarity of the work metals.

In the three examples that follow, the differing properties of the two work metals were the major factors in determining welding procedure.

Example 497. Welding Type 304 Stainless Steel to Oxygen-Free Copper (Fig. 52)

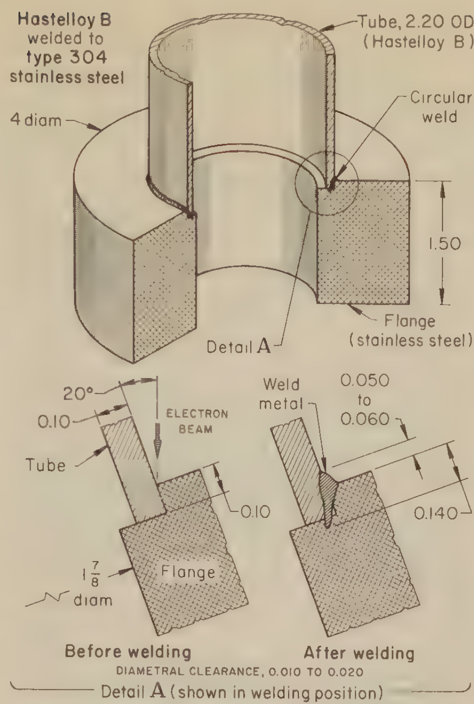
An electron beam welded joint between copper and stainless steel piping of a pressure cooling system was required to be leaktight. The components of the joint (Fig. 52) consisted of a nozzle or flanged tube made of oxygen-free copper and a short length of type 304 stainless steel tubing. Chief considerations in welding the two metals were (*a*) possible expulsion of gas during melting of the copper, and (*b*) the wide difference in properties, such as thermal conductivity, thermal expansion, and melting temperature. Helium mass spectrometry was specified for determining leaktightness of completed welds.

Figure 52 shows the double-rabbeted joint design that was used to provide self-alignment, with the assistance of a simple holding fixture. The beam was aligned to impinge 0.015 in. on the copper side of the joint (section A-A in Fig. 52). Joint penetration was accomplished in a single pass by rotating the assembly under a fixed gun, using the conditions given with Fig. 52. Although gas evolution during welding was not a serious problem, some copper was expelled, resulting in irregularity of the weld surface. A cosmetic pass was made, to smooth the weld, immediately after the principal welding pass by defocusing the beam and manually reducing the beam power, visually observing the effect during the adjustment.

Example 498. Welding of 1113 Steel to Aluminum Alloy 2024-T4, Using a Silver Transition Ring (Fig. 53)

It became necessary to develop a procedure for hermetically sealing an electrical connector housing made of 1113 steel to an enclosure made of aluminum alloy 2024-T4

*See pages 47.40 to 47.43 in Section 3A of "Welding Handbook", 6th Ed., AWS, 1970.



Joint type	Circular corner; rabbeted, self-backing
Weld type	Square groove with fillet
Machine capacity	50 kv at 250 ma
Gun type	Diode; fixed during welding
Vacuum chamber	Steel; 54 by 48 by 48 in.
Fixtures	Part-holding tool for 16 pieces, with individual rotation; table with *x-y* motion
Filler metal	None
Welding power	24 kv at 70 ma
Welding vacuum	5×10^{-5} torr
Pumpdown time	10 min
Working distance	About 4⅛ in.
Beam focal point	On, or slightly above, workpiece junction
Welding speed	60.7 ipm
Number of passes	One, plus 220° downslope
Heat input	1.67 kilojoules per inch
Preheat and postheat	None

Fig. 54. Welding of type 304 stainless steel to Hastelloy B (Example 499)

(Fig. 53). Neither arc welding nor brazing was suitable, as the glass-to-metal seal of the tiny plate and the delicate internal components of the package could not withstand the heat cycling, and electron beam welding was therefore selected.

The metallurgical incompatibility and the differences in thermal expansion, thermal conductivity and melting point of the steel and the aluminum alloy required the use of a transition metal in welding the joint. In addition, the 1113 steel, which had been selected for its free-machining properties, was a resulfurized type (0.24 to 0.33 sulfur), and therefore difficult to weld.

Commercially fine silver (99.9 min silver) was chosen for the transition metal because of its metallurgical compatibility with iron and aluminum, and because it (*a*) was very ductile, malleable and of sufficient strength; (*b*) had a melting point intermediate between aluminum and steel; (*c*) was quickly obtainable; and (*d*) had been used successfully under somewhat similar conditions.

The silver ring, as shown in Fig. 53, was designed to be joined to the steel component by a circular square-groove butt weld (weld A) and to the aluminum alloy component by a circular fillet weld (weld B). The ring was press fitted into a groove machined in the aluminum plate, and the steel plate was press fitted to the silver ring (Fig. 53, detail A). Neither preheat nor postheat was used. Both welds were made on the turntable of a welding positioner constructed for accurate control of position and rotation.

Welding procedures (see the table with Fig. 53) were set up on the basis of trial and error. Under the pressure of time, if a technique or machine setting worked, it was adopted, even though further development held promise of improvement.

For the steel-to-silver butt weld, the most favorable beam alignment was directly on the joint. When the beam was directed on the steel side of the joint, pinholes, which resulted from the sulfur content, made the weld completely unacceptable. When the beam was directed on the silver side, weld appearance was good, but rejections on leak testing were too high. Using the settings shown in the table with Fig. 53 and a beam aligned directly on the joint, the acceptance rate for this weld averaged about 70%. Later tests indicated that an unresulfurized steel would have produced greater joint reliability.

The aluminum-to-silver fillet weld was made by inclining the positioner turntable so that the beam impinged on the root of the joint at an angle of 20°, as shown in Fig. 53, detail A. The fillet weld was satisfactorily produced, with good repeatability.

Weld configurations, as shown in detail A, indicated adequate joint penetration. Where leaks were detected during helium leak testing, the defects were repaired by rewelding. Repeated rewelding, however, sometimes caused cracking of the steel-to-silver weld.

Example 499. Joining Type 304 Stainless Steel to Hastelloy B With Loose Fit-up and Automatic Downslope Control (Fig. 54)

The joint shown in Fig. 54 consisted of a 2.20-in.-OD Hastelloy B tube set into a type 304 stainless steel ring flange. After welding, the joint was required to prove a leak rate of less than 1×10^{-8} cu cm per second by mass-spectrometer testing. Requirements had been met by gas tungsten-arc welding, but because of the availability of an electron beam welding machine for other work (see Example 476) and the desire for increased production, a procedure for electron beam welding was developed.

Cryogenic service conditions determined selection of work metals, and influenced welding procedure. The weldment was part of the equipment used on bulk storage tanks for liquefied gases.

Although interference fits are frequently used to prevent cracking in a restrained circular joint, use of an interference fit in this joint resulted in a hairline crack running circumferentially around the weld. The cracking was ascribed to a number of factors, including large differences in mass, thermal conductivity, and thermal expansion and contraction, and the properties of the weld-metal alloy. It was found that a satisfactory weld could be made if the joint had a diametral clearance of 0.010 to 0.020 in.

Optimum weld contour was obtained by aligning the beam at an angle of 20° to the Hastelloy B tube, with the beam focal point on, or slightly above, the junction of the two members, as shown in Fig. 54. Because macrosections showed that sometimes the electron beam weld did not penetrate to the lower inside corner of the joint, tests were run to compare the strength of such a weld with that of the fillet welds previously made by the gas tungsten-arc process. The results of a reverse-bending fatigue test indicated that the electron beam weld, with partial joint fusion, was stronger than the arc fillet weld.

The electron beam welding machine used in this application was the same as that used in Example 476. A multiple-part rotating fixture was designed to hold and rotate 16 parts individually. Welding conditions used in the operation are given in the table with Fig. 54.

The use of automatic downslope was a critical feature of the welding cycle. Power upslope control was relatively unimportant. At the point of crossover, after one revolution, it was necessary to downslope the power to zero over an additional 220° of revolution to prevent weld cracking.

Figure 54, detail A, shows the weld contour that was usually obtained. Less than 0.5% of the parts were rejected on mass-spectrometer inspection; most rejected parts could be repaired by rewelding.

Electron Beam Welding vs Alternative Processes

The chief advantage of electron beam welding over other welding processes is its ability to make deep, narrow, closely controlled welds in a single pass, with low total heat input and with an extremely short heat-melt-cool cycle (see the sections on Applicability, page 519, and Welding of Complex Assemblies, page 531). Other advantages include high welding speed, ability to make most welds without using filler metal or shielding gas, and applicability to welding in deep, narrow recesses or locations close to other components that are heat-sensitive, or that obstruct access for arc welding.

Major disadvantages of electron beam welding, as pointed out in the section on Applicability, page 519, and in the Appendix to this article, include high equipment cost, high cost of precision joint preparation and precision tooling, and limitations on work size and unit production time when welding is done in a vacuum chamber. Another drawback is that electron beam welds are somewhat more susceptible than arc welds to cold shuts and root voids — particularly welds ½ in. deep or more.

In a survey on selection of welding processes, the major reasons given for choosing electron beam welding in preference to other welding processes were improvement in mechanical properties of joints, reduced distortion, cost reduction, and unique applicability for welding specific assemblies. In more than half of the examples of practice in this article, joint requirements could be met in a practical way only by electron beam welding.

The six examples that follow describe applications for which electron beam welding was selected rather than another fabricating process.

Example 500. Electron Beam vs Gas Tungsten-Arc Welding of D-6ac Missile Cases (Table 4)

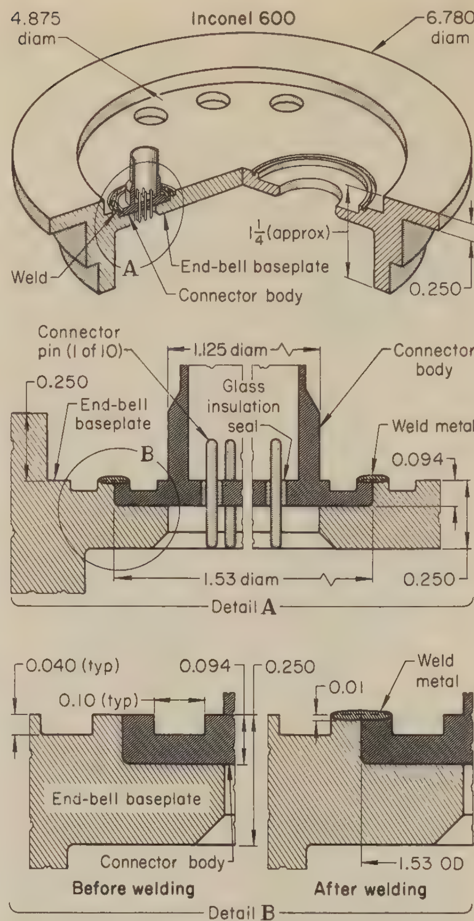
Early experience of one manufacturer in fabricating D-6ac missile cases by automatic gas tungsten-arc welding proved discouraging. The missile cases, which were 6 in. in diameter and 0.040 in. thick, required two girth seams to join the end closures to the shell. Weld porosity was a continuous problem — about 10% of the cases required time-consuming weld repairs to remove defects revealed by radiography. Fractures in hydrostatic burst tests usually started at the weld. Similar tests on cases welded by the electron beam process showed that fractures were not generally associated with the weld.

Pilot runs using electron beam welding showed several advantages. The component parts could be finish machined and then welded, with less than 0.003 in. change in diameter at the weld area. Preheating was not required, welding was faster and was done without pressurized internal backing, and alignment of the square butt joint was achieved by an external hinged ring. After the ring was removed, surface friction maintained alignment until welding was completed.

Only simple end-thrust fixturing was needed. In addition, the appearance of completed welds was sufficiently attractive to eliminate the need for machining. Required quality was ensured by three electron beam penetration passes plus a cosmetic pass. Hardened stock was first used, but was replaced by normalized stock for easier postweld machining.

The success of the electron beam procedure led to a study that projected total costs for the two processes over five years. The results, as shown in Table 4, indicated that electron beam welding was less expensive, based on continuous production welding of the same 6-in. missile cases.

In actual production for a period of six years, the validity of the cost projection was verified, and the electron beam welding procedure showed advantages not included in the original projection. Weld repairs for the removal of defects revealed by radiography were made on less than 5% of the missile cases welded, as compared with a 10% rate with gas tungsten-arc welding. In addition, the repair procedure consisted merely of remelting the weld with the electron beam. The arc weld defects generally had to be ground out and the cavity filled, using filler wire.



Joint type	Circular edge
Weld type	Seal; shallow square groove
Machine capacity	30 kw
Gun type	Pierce; fixed
Filament	Square tantalum ribbon
Vacuum chamber	Stainless clad; 50 by 30 by 42 in.
Vacuum pumps:	
Roughing	140 cfm
Holding	3.5 cfm
Diffusion	10^4 liters per sec at 10^{-4} torr
Fixtures	Three-jaw chuck; holding clamp
Welding power	15 kv at 15 ma
Welding vacuum	10^{-4} torr
Welding speed	35 ipm
Pumpdown time	4 min
Production time	5 min per weld (10 min per assembly)

Electron beam welding, using a heat input of 0.39 kilojoules per inch of weld length, was used instead of gas tungsten-arc welding, to avoid cracks in the welds and nearby glass seals.

Fig. 55. Portion of a welded end-bell assembly for a liquid-metal pump (Example 501)

Example 501. Selection of Electron Beam Instead of Gas Tungsten-Arc Welding To Avoid Heat Damage in Hermetic Sealing of Electrical Components (Fig. 55)

End-bell assemblies for liquid-metal pumps required the welding of two electrical connector bodies to the end-bell baseplate made of heat-resisting alloy Inconel 600. One connector body was made of type 304 stainless steel and contained two connector pins; the other, shown in detail in Fig. 55, was made of Inconel 600 and contained ten connector pins. The metal pins were insulated from connector bodies by glass seals, which were tested for leak rates not to exceed 10^{-8} cu cm per second under 15-psi differential helium pressure, using a mass spectrometer. The welding objective was to obtain completed assemblies having leak rates not exceeding 10^{-7} cu cm per second; hence, weld cracking, weld porosity, and cracking of the glass seals could not be tolerated.

Joint preparation, as shown in Fig. 55, consisted of machining a circular groove near the mating edge of each component part. This type of joint served to (*a*) reduce heat-input requirements by partially isolating the weld, (*b*) reduce heat transfer to the components, and (*c*) avoid high residual stress by yielding slightly under shrinkage stress during cooling.

Welding was originally attempted by using a gas tungsten-arc torch to fuse the joint edges, without a filler-metal addition. These assemblies could not meet leak-rate requirements because small cracks occurred in the welds and the glass seals.

Satisfactory welds were obtained when the procedure was changed to electron beam welding. Higher welding speeds and smaller fusion zones resulted in lower heat input (0.39 kilojoules per inch of weld length). Fixturing was relatively simple, consisting of a holding tool made from a steel bar held by a rotating three-jaw chuck. Because joint penetration of only 10% was required, chill bars were not needed to prevent overheating.

The sequence of operations was as follows. After machining, the parts were degreased, thoroughly cleaned, and dried. One connector body was assembled and fixtured, and the chamber was pumped down. The connector body was tack welded at 0°, 180° and 90°; welding was then started at 270°. After the first connector body was welded, the assembly was removed from the chamber, and the operation was repeated for the second connector body.

Equipment details and welding conditions are given in the table with Fig. 55.

Example 502. Results Obtained by Gas Tungsten-Arc Welding, Furnace Brazing and Electron Beam Welding on Highly Restrained Joints in Beryllium Copper (Fig. 56)

Specifications for a two-piece, copper alloy water jacket permitted the use of gas tungsten-arc welding, furnace brazing or electron beam welding for joining the jacket cover plate to the cast jacket body. As shown at the top of Fig. 56, the cover plate was a flat, annular ring set into the cast body. Joints at the inner and outer periphery, as well as at the eight ribs that served as baffles and reinforcement, were required to be watertight. Water jackets were pressure tested at 50 psi with argon.

Copper alloy 175, high-conductivity beryllium copper (96.9 Cu, 2.5 Co, 0.6 Be), was selected for its combination of thermal conductivity and fatigue strength. The best combination of properties for welding was produced by solution annealing at 1700 F, water quenching, and age hardening at 900 F for 3 to 4 hr. In the age-hardened condition, the material had a tensile strength of 100,000 psi and relative thermal conductivity of 59% (see Table 1 on page 338).

Gas tungsten-arc welding (process A) was initially selected for joining the parts because it had been used on the same ma-

terial in other applications and the equipment was available. Filler metal was copper alloy 172, high-strength beryllium copper, having a nominal composition of 98.1 Cu, 1.9 Be. Joint design called for an 80° V-groove with a 1/16-in. root face for the two circular welds and two 3/8-in. plug welds on each of the eight ribs. The machined and heat treated parts were assembled and preheated to 800 F. Joints were aligned by placing four C-clamps over the ribs and moving the clamps to adjoining ribs as the circular root passes and the plug welds were made. Root passes were made by staggering narrow beads in 1-in.-long increments until all beads were connected. The clamps were removed, and staggered filler passes were made around the two circular joints, and the plug welds were completed. The groove welds were completed with a cover pass. Interpass temperature was maintained at about 800 F by gas torch and welding heat. After welding, the assembly was heated for 3 hr at 800 F.

Although the procedure had been successful for other applications, cracking occurred in the weld and the base metal, because of the high restraint imposed by the two circular welds. Gas tungsten-arc welding with alternating and direct current was tried, without success, and this welding process was abandoned.

Furnace brazing (process B) using a silver alloy filler metal, proved satisfactory, although the procedure was somewhat lengthy and lower base-metal properties had to be accepted, because heat treatment after brazing was impractical. After the parts had been chemically cleaned, surfaces to be joined were silver plated. Brazing strip 0.003 in. thick, of AMS 4772 (AWS BAg-13, having a nominal composition of 54 Ag, 40 Cu, 5 Zn, 1 Ni), was cut to just overlap the areas to be brazed, and the individual pieces, painted with flux, were attached to the casting surface by small resistance spot welds. BAg-13, which has a liquidus of 1575 F and a solidus of 1325 F, was selected for this application after several eutectic, or near eutectic, Ag-Cu-type alloys were tested and rejected.

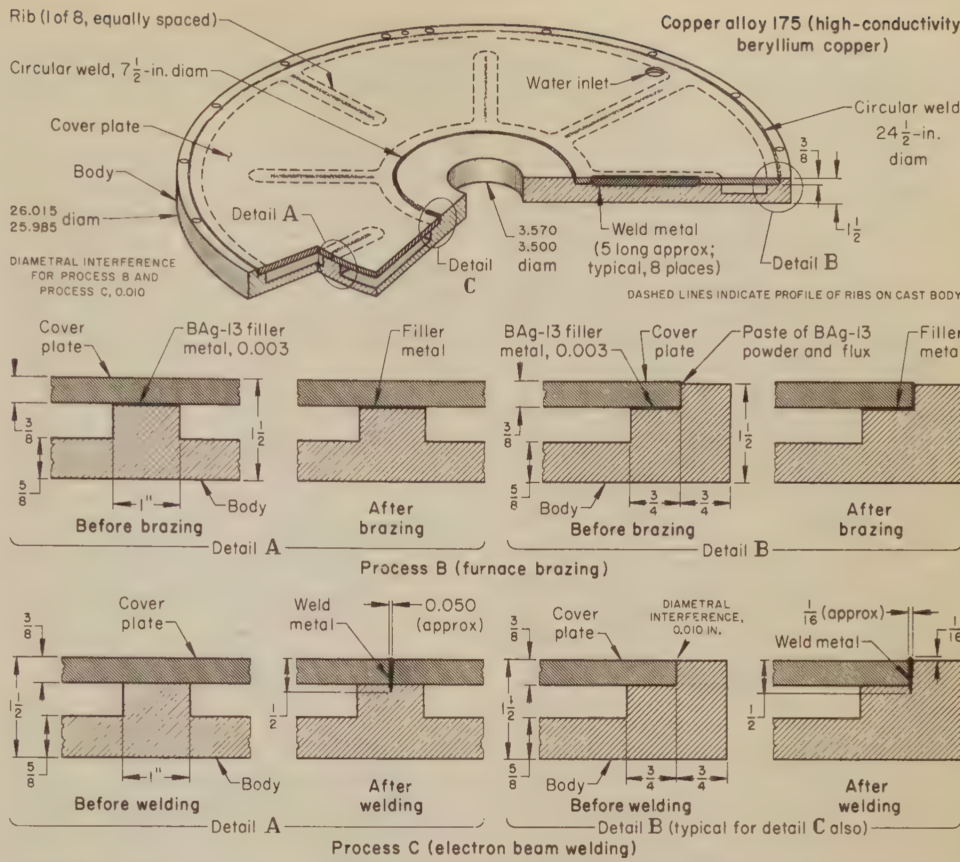
The flat cover plate was then placed on the cast body and brazing powder mixed with flux and water was applied with an eyedropper at the top of the butt joints. Detail views of the joints for process B (furnace brazing), before and after brazing, are shown at the middle in Fig. 56. The circular butt joints were dimensioned for 0.010-in. diametral interference.

The workpieces were loaded into a furnace on a flat graphite plate with the cover side up. Graphite blocks were placed on the cover and weights totaling about 400 lb were stacked on the blocks to hold the joint surfaces in intimate contact.

The assembly was heated to 1700 F in a muffle containing dry hydrogen (dew point, −50 F), was allowed to soak for 20 min, and was then cooled to 1575 F and held for 2 hr at that temperature to obtain further diffusion of the brazing filler metal into the copper alloy. The vertical muffle, with the brazed workpiece, was then removed from the furnace and allowed to cool while being purged with hydrogen. After brazing, the assembly was sand blasted and finish machined.

Electron beam welding (process C) produced the most satisfactory results. Silver plating was not needed, and the maximum heat treated strengths of the finished parts were retained. To prevent cracking in the two circular square-groove butt welds, the cast body and the cover plate were machined to provide a 0.010-in. interference fit, so that the assembled joints were under compressive stress. Joint details for process C are shown at the bottom of Fig. 56.

Welding was done with a general-purpose electron beam welding machine. The welding was done at high vacuum. C-clamps were placed over four ribs, and 1-in.-long tack welds were made at the two butt joints. Four 5-in.-long melt-through (spike) welds were made on the ribs, as shown in Fig. 56. The clamps were moved



Furnace Brazing Conditions

Furnace	Batch type
Atmosphere	Dry hydrogen (−50 F dew point)
Joint preparation	Joint surfaces silver plated
Filler metal	0.003-in.-thick silver alloy strip; also brazing powder mixed with flux and water, AMS 4772 (AWS BAg-13)
Temperature cycle	Heat to 1700 F, soak 20 min; cool to 1575 F, soak 2 hr; remove muffle, cool, H_2 purge

Electron Beam Welding Conditions

Joint types	Circular butt; lap
Weld types	Square groove; melt-through (spike)
Machine capacity	150 kv at 40 ma
Vacuum-chamber size	56 by 56 by 60 in.
Joint preparation	0.010-in. diametral interference
Filler metal	None
Welding power:	
Square-groove welds	150 kv at 50 ma
Melt-through welds	150 kv at 40 ma
Welding vacuum	10^{-4} to 10^{-5} torr
Welding speed:	
Square-groove welds	20 ipm
Melt-through welds	30 ipm
Preheat	None
Postheat	850 F stress-relief and age-hardening treatment

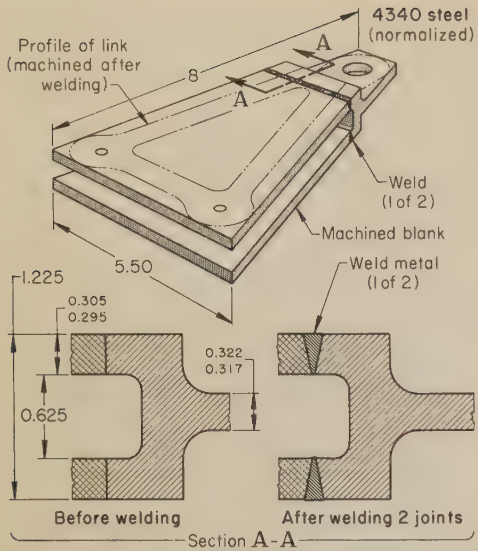
Fig. 56. Water jacket that was satisfactorily joined by furnace brazing (process B) and most successfully by electron beam welding (process C), and sectional views of joints before and after brazing and welding. Gas tungsten-arc welding (process A; not shown) was tried, but could not be used because of weld cracking, caused by high joint restraint. (Example 502)

to the second set of ribs and the welding procedure was repeated. The clamps were then removed and the circular square-groove welds were completed. A postweld heat treatment at 850 F was given to the assembly to age harden the weld area and

Table 4. Five-Year Cost Projection for Electron Beam and Automatic Gas Tungsten-Arc Welding of 6-In.-Diam D-6ac Steel Missile Cases (Example 500)

Item	Electron beam welding	Gas tungsten-arc welding
Production rate, parts per hour	28(a)	8(b)
Amortization cost (5 years):		
Welding machine	$ 85,000	$ 20,000
Pressurized backup tooling	...	12,000
Automatic indexing tooling	15,000	...
Interest at 5%	25,000	8,000
Consumables (5 years):		
Shielding gas, $2.25 per hour	...	10,125
Tungsten electrodes, one per week	...	325
Filaments, one per week	2,500	...
Spare parts, 1% cost per year	5,000	1,600
Power, $0.02 per kilowatt-hour	4,500	865
Labor (10,000 hr):		
Operator, at $7.00 per hour	70,000	70,000
Helper, at $5.00 per hour	50,000	...
Total(c)	$257,000	$122,915
Parts produced (9000 hr)	252,000	72,000
Cost per part	$1.02	$1.71

(a) Includes loading eight parts every 16 min, vacuum pumpdown, welding two circumferential joints, and unloading fixture. (b) Includes loading part in fixture, preheating, welding two circumferential joints, and unloading fixture. (c) Total does not include the cost of reworking rejects.



Joint	Butt
Weld type	Square groove
Machine capacity	150 kv at 40 ma
Gun type	Fixed
Vacuum-chamber size	56 by 56 by 108 in.
Maximum vacuum	10^{-5} torr
Fixture	Clamping jig with 180° rotation
Preheat	None
Welding power	130 kv at 24 ma
Welding vacuum	Less than 10^{-4} torr
Beam focal point	0.250 in. above work surface
Beam oscillation	Circular, 800 hertz
Welding speed	36 ipm
Welding time	4.2 sec per leg
Production rate	1 hr per batch of eight pieces(a)
Postheat	Stress relieve at 950 F for ½ hr; heat treat (see text)

(a) Includes loading, pumpdown, welding and unloading. Monthly production ranged from 40 to 80 pieces.

Fig. 57. Three-piece machined-and-welded link that replaced a one-piece machined link (Example 503)

stress relieve the weldment. The weldment was then air cooled and machined to size.

Data for the furnace brazing and electron beam welding procedures are summarized in the table accompanying Fig. 56. A total of 15 assemblies were joined by electron beam welding.

Example 503. Machining Plus Electron Beam Welding vs Machining for Production of a Steel Link (Fig. 57)

A link, formerly machined from a 1⅜-in.-thick 4340 steel plate, was replaced by an electron beam welded assembly to reduce machining costs. Electron beam welding was chosen instead of arc welding because it consistently provided high joint efficiency and low distortion, especially in welding 4340 steel. The top view in Fig. 57 shows the as-welded blank before machining the final profile, indicated by the phantom line.

With the original one-piece machined link, rejection rate had been high and cutter costs for milling the deep slot between the legs were also high. Machining of the slot was unnecessary when electron beam welding was used. The link blank was made by welding two legs made of ⅜-in. plate and a tongue made of a 1⅜-in.-thick bar, all of normalized 4340 steel. Legs and tongue were finish machined on the top and bottom surfaces to the dimensions shown in Fig. 57. The square-groove butt joints were machine ground, and the parts were then demagnetized. To provide starting and runoff material for welding, the final profile was not machined until after welding was completed.

Before assembly, the parts were vapor degreased and wiped with acetone or methyl ethyl ketone. To permit welding a batch of eight link assemblies during one pumpdown, special clamping jigs were used. Five holes served to position the parts, and a spacer positioned the legs to hold the slot tolerance. The jigged assemblies were mounted in a rotary fixture to permit turning the part over for welding both sides in one pumpdown. Fit-up tolerances, including surface mismatch, were held to 0.005 in. max. Weld traverse was obtained by motion of the holding fixture, while the beam was circularly oscillated at a frequency of 800 hertz.

Details of the machine settings and other welding conditions are given in the table with Fig. 57. After welding, the parts were immediately stress relieved, and then heat treated to a tensile strength of 150,000 to 172,000 psi. A light finish cut was then taken to clean off the weld surface. The welds were examined by magnetic-particle, radiographic and ultrasonic inspection.

Occasionally, it was impossible to machine the top surface of the weld flush, as a result of undercutting. This condition could be detected by visual inspection of the weld surface before removal of the part from the welding chamber, and was corrected by making a cosmetic pass, using a defocused beam. Filler metal was not used.

Changing from all machining to electron beam welding and machining resulted in savings of approximately $50 per piece.

Example 504. Use of Electron Beam Welding To Make Double-Helical Gears With Close Spacing (Fig. 58)

A planetary-gear transmission included five different sizes of double-helical gears of two-piece welded construction. The gears were precision machined and ground from case hardened AMS 6265, a vacuum-melted alloy steel of composition similar to that of 9310. Figure 58 shows a 5.700-in.-OD 38-tooth gear, fabrication of which was typical of the other sizes produced. Two-piece welded construction made it possible to produce double-helical gears of narrow width, low weight and high joint strength. Gear teeth had to be completely finished before assembly, because the closeness of the helixes prevented tool access after assembly. Although mechanical joining could have produced a narrower gear, joint strength would have been inadequate.

Electron beam welding was selected because it was the only process that could produce full joint penetration in a single pass and that had a low enough heat input to avoid distortion. Mating requirements of the helical teeth left extremely little margin for error, and the only machining necessary after welding was reboring of the inside diameter of the gear, finishing of the weld face, and light grinding of the sides of the gear assembly to meet tolerances on over-all width.

In making the double-helical gears, gear halves were machined and case hardened, and tooth surfaces were finish ground to size. The case was ground from the surfaces to be welded. Parts were vapor degreased and rinsed in methyl ethyl ketone.

The gear halves were then assembled in a laboratory, using special gear-measuring equipment. The parts were aligned on a mandrel with the aid of a ¼-in.-square backing-and-alignment ring, which was located as shown in section A-A of Fig. 58. Tooth-to-tooth spacing and lead variation between the two helixes were held within a maximum 0.0002-in. tolerance.

The assembly was loaded into the vacuum chamber, with the mandrel centered on a rotating drive. During pumpdown, the joint was accurately positioned under the fixed electron beam for rotation about the horizontal axis of the gear assembly.

Machine settings for the welding cycle were established by welding test pieces, to ensure ⅛-in. penetration into the backing ring. Maximum combined width of weld and heat-affected zone on each side of the weld was less than 0.125 in. Machine settings and other welding conditions are summarized in the table accompanying Fig. 58. Figure 58 shows details of the joint, backing ring, and completed weld.

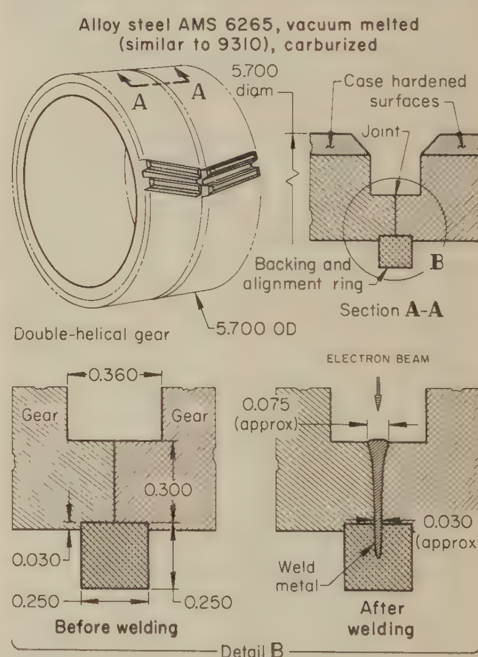
After welding, the entire assembly was heated at 300 F for 3 hr, and the mandrel was removed. The backing ring was removed by machining, and the weld face was machined off for inspection. Dimensions were checked, using the same equipment used for alignment. Welds were examined visually and by magnetic-particle, radiographic or ultrasonic inspection. The bore was finish machined and the sides lightly ground to width tolerance.

The entire production was ten gear assemblies of each of the five sizes, for a total of 50 gear assemblies. To facilitate replacement of parts, gears of any one size had to be interchangeable.

Example 505. Compact Design of Carburized Alloy Steel Aircraft Spur Ring Gear Made Possible by Low Distortion and Low Heat Input of Electron Beam Welding (Fig. 59)

An aircraft spur ring gear, made of AMS 6260 alloy steel (9310), was designed in two pieces for electron beam welding. Two-piece construction overcame design limitations of space and weight, because additional stock was not needed to grind the external gear. The two pieces were machined, carburized, hardened and tempered, and then were electron beam welded without dimensional distortion or damage to hardened surfaces.

Before welding, the joint surfaces were ground for an interference fit. From the standpoint of distortion and heat damage during welding, the critical areas were the two gear surfaces and the internal bearing-race surface, the most critical being the



Joint type	Circumferential butt
Weld type	Square groove, with backing ring
Machine capacity	150 kv at 40 ma
Gun type	Fixed
Vacuum-chamber size	52 by 36 in. by 36 in. high
Maximum vacuum	10^{-6} torr
Fixtures	Aligning and backing ring on mandrel; rotating drive
Welding power	127 kv at 19.7 ma
Welding vacuum:	
During setup	2×10^{-4} torr max
During welding	5×10^{-5} torr
Working distance	6.0 in.
Beam focal point	At surface
Beam spot size	0.015 in.
Welding speed	30 ipm
Preheat	None
Postheat	300 F for 3 hr

Fig. 58. Double-helical gear, showing two-piece construction that was possible only by electron beam welding after the gear teeth had been case hardened and finish ground to size (Example 504)

bearing-race surface, which paralleled the joint and was separated from it by only ⅛ in. Minimum hardness requirements for the race, before and after welding, were Rockwell C 58 and 56, respectively. After welding, the assembly was heated at low temperature and finish ground to size.

For optimum heating efficiency, a narrow, sharply defined beam was required, and therefore the gun was equipped with a special copper anode to minimize the heat effect of fringe electrons in the beam. In addition, a dual-gap focusing coil was installed to minimize beam width. Copper chills, which had been soaked in dry ice and fixtured to the assembly (Fig. 59, top view) about 10 min before welding, served to dissipate heat and to hold critical dimensions. Other features of the procedure, as described below, were based on producing one gear per chamber pumpdown.

After machining, the gear teeth and bearing-race surface were carburized, hardened and tempered to Rockwell C 58. Weld-joint surfaces were machine ground and polished with an abrasive-impregnated rubber stick to obtain a 0.0002-to-0.0008-in. interference fit. Surface film was removed in four steps: (*a*) dip in cold trichlorethylene, (*b*) sonic clean in trichlorethylene at 150 F for 5 min, (*c*) sonic clean in methyl ethyl ketone for 5 min, and (*d*) oven dry at 150 F. Both parts were demagnetized.

Next, the parts were assembled by heating the outer piece to 300 F. When it was cool, the joint was encased in the copper chills and the assembly was mounted on a turntable in the vacuum chamber. Under vacuum, the beam was aligned at low power, using a working distance of 5½ in. Runout was held to 0.002 in. max.

The beam, which had a focal-length range of 2 to 15 in., was adjusted by first obtaining a sharp focus on the joint surface and then reducing the focal length slightly by decreasing the focus current by 0.10 amp. The turntable was set for rotation at 13.6 rpm, causing the 6.23-in. length of joint to traverse the beam at 85 ipm.

Welding was done using the machine settings given in the table with Fig. 59. These settings were previously determined by welding a solid plate to obtain the 0.300-in. minimum joint penetration required. Welding current was adjusted for automatic upslope and downslope. Full power was used for slightly more than one revolution. Sloping the current at start and finish resulted in a complete weld in 1.71 revolutions.

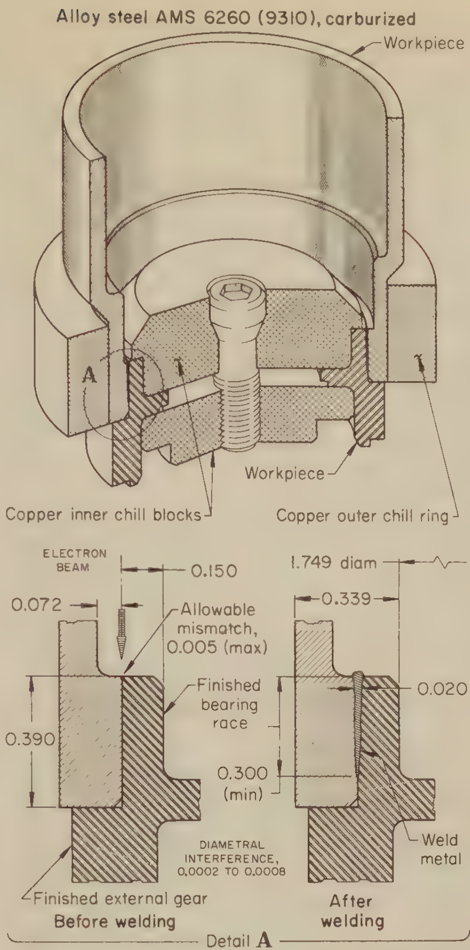
Welded assemblies were heated at 300 F for 2 hr, after which they were finish ground to size. Acceptance criteria were based on two methods of inspection. The first method involved removing two samples from the initial production lot for destructive testing. Parts were required to show 0.300-in. minimum joint penetration, with no cracks. A small amount of porosity was acceptable.

In the second method, nondestructive testing was used. All parts were ultrasonically inspected for cracks and voids, with permanent records being made by print-out of the scan. In service, weld strength was more than adequate.

Safety

Protection must be provided by equipment design and arrangement, and by safety precautions, in electron beam welding and related operations, against the usual hazards of welding and the special hazards of exposure to (*a*) the high voltages involved in generating the electron beam, (*b*) the beam itself, and (*c*) radiation of x-rays produced by impingement of the beam on the work or other materials.

Suitable precautionary measures are described in AWS A6.4, Recommended Safe Practices for Electron Beam Welding, and in ANSI Z49.1, Safety in Welding and Cutting.



Joint type	Circular butt; rabbeted, self-backing
Weld type	Square groove
Machine capacity	60 kv at 500 ma
Gun type	Pierce; triode; fixed vertical position(a)
Special equipment	Copper anode to reduce fringe electrons; dual-gap focus coil for narrow beam
Maximum vacuum	5×10^{-5} torr
Vacuum-chamber size	50 by 30 by 42 in.
Fixtures	Holding clamp, turntable, copper chills
Welding power	58.5 kv at 65 ma
Filament voltage	170 v
Welding vacuum	5×10^{-4} torr
Pumpdown time	5 min
Working distance	5½ in.
Beam focal point	Slightly defocused at surface
Beam spot size	0.020-in. diameter
Power density	12.2 megawatts per square inch
Welding speed	85 ipm
Postheat	300 F for 2 hr
Production rate	7 pieces per hour(b)

(a) Neutral-field cathode was made from steel of high magnetic permeability. Tantalum filament had an estimated life of 100 hr. (b) Includes cleaning, assembly, loading, pumpdown, welding and unloading. Chamber was loaded with one assembly at a time.

APPENDIX

Cost of Electron Beam Welding

The major factors that influence the cost of electron beam welding are high equipment cost, effect of pumpdown time on unit labor cost, and high cost of precise joint preparation and precision tooling.

Equipment Cost. The initial cost of electron beam welding equipment varies considerably, depending on chamber size, type and capacity of vacuum-pumping equipment, beam-power requirements, and degree of complexity and automation of control equipment.

Cost of a general-purpose electron beam welding system, including a relatively simple, powered worktable for translational motion and a lathe-type rotary fixture, is seldom less than $100,000 (see Example 500); cost of more complex systems may be several times this amount, especially with highly refined control and work-handling mechanisms. The absence of a welding chamber in nonvacuum systems is offset, at least in part, by the cost of a shielded work enclosure and high-speed work-handling equipment.

High equipment utilization, preferably in long runs on similar parts, is needed to avoid high amortization charges in unit welding costs.

Pumpdown Time and Labor Cost. A second major factor in electron beam welding cost is the effect of pumpdown time on labor cost per weld (see the discussion of pumpdown on page 521). This effect can be reduced in some applications by using work chambers of minimum size for the assembly being welded, increasing pumping capacity, welding in medium vacuum instead of high vacuum, using dual work chambers or special, vacuum, rotary feed systems with sliding seals, and by other mechanical expedients. Pumpdown time is eliminated in nonvacuum welding, but this method is not applicable for deep, narrow welds.

Cost of Joint Preparation and Tooling. A third major cost factor is the high cost of precise joint preparation and of the precision tooling needed for accurate tracking of the joint by the narrow electron beam.

Favorable Cost Factors. Factors that favor the use of electron beam welding where arc welding is also suitable include high welding speed, deep penetration in a single pass, and the ability to make most welds without using filler metal or shielding gas. In many applications, the localized heat input and extremely rapid thermal cycling of electron beam welding eliminate, or reduce, the cost of related operations such as machining and heat treatment.

Cost Factors in Examples. In Example 466, welding time was reduced, and preheating and two machining operations were eliminated by changing from gas metal-arc to electron beam welding of steam-turbine diaphragms, reducing fabricating time from 17 to 4.75 hr. In Example 503, changing from a one-piece machined part to a three-piece electron beam welded assembly eliminated the milling of a deep slot for a saving of about $50 per piece.

In Example 500, 0.040-in.-wall D-6ac missile cases were fabricated at lower cost by electron beam welding than by gas tungsten-arc welding. The major cost factor was faster production by the electron beam method, which was done at higher welding speed and (unlike the arc method) without preheating. Additional cost advantages not included in the table of cost data for this example were the elimination of

finish machining of the weld face and root, fewer weld repairs, and a less expensive repair procedure for electron beam welding.

Cost of Commercial Welding Services. A survey on prices charged for electron beam welding by job shops has shown charges of from \$25 to \$100 per pumpdown, plus \$0.50 to \$1.50 per weld. The basis for pricing may be a flat rate per hour that includes all services, an hourly rate plus a pumpdown charge, a rate per lineal foot of weld, or variations of these.

Cost Study: Electron Beam vs Gas-Shielded Arc Welding*

Table 5 shows estimated total cost and a detailed cost breakdown developed in a study on the welding of two domed heads on a 24-in.-diam, 36-in.-long cylinder in ¼-in. and 1-in. thicknesses. The analysis was performed for maraging steel, HP 9-4-25 high-strength alloy steel, and Ti-6Al-4V. For 1-in. plate, the analysis showed that the cost of electron beam welding was approximately one-fourth the cost of gas metal-arc welding and one-fifth the cost of gas tungsten-arc welding. For ¼-in. plate, the cost of electron beam welding was slightly less than the cost of arc welding. The two main factors that increased the cost of arc welding the 1-in. plate were the time required to deposit multiple passes, and the cost of the filler wire.

Table 5. Estimated Cost To Weld a 24-In.-Diam Cylinder to an End Dome by Electron Beam, Gas Tungsten-Arc and Gas Metal-Arc Welding (a)

Set up, weld and clean, min:					
¼-in. plate	85	39	86	57	35
1-in. plate	706	280	704	444	243

Welding Conditions. Joint preparation assumed for the arc welds was a 90° single-V groove and 1/16-in. root face for the ¼-in. plate, and a 30° single-U groove (¼-in. root radius) and ⅛-in. root face for the 1-in. plate. Groove volume per inch was 0.0352 cu in. and 0.515 cu in., respectively.

Operating conditions assumed for electron beam welding in this cost analysis are given in Table 6. The conditions for the 1-in. material were developed experimentally in this study, and those for the ¼-in. material were based on experimental data obtained in the study and on published data. Lower speeds were used for the HP 9-4-25 steel than for the maraging steel, to avoid porous welds in the HP 9-4-25.

The operating conditions assumed for gas tungsten-arc and gas metal-arc welding are listed in Table 7. They were based on general practice in arc welding these materials and a review of the technical literature.

Equipment Cost. For this analysis, the cost of the electron beam welding machine was estimated to be \$120,000 and to be written off over a ten-year period, at a rate of \$1000 per month, or \$6.20 per hour. The arc welding equipment, for either arc method, was estimated to cost \$12,000 and to be written off in a ten-year period at a rate of \$100 per month, or \$0.62 per hour. The equipment contribution to the cost of welding by either method was based on the total time the equipment was required for setup, making the weld, and cleaning after welding.

Labor and Overhead Costs. Assumed hourly costs of labor and overhead for each operation are:

	Electron beam welding	Arc welding
Welding operator:		
Labor, per hour	\$ 3.50	\$ 3.00
Overhead, per hour	11.20	5.62
Machinists, including overhead, per hour	10.00	10.00
Inspectors, including overhead, per hour	10.00	10.00

The electron beam welding overhead rate was based on a general factory overhead rate of \$5 per hour plus \$6.20 per hour write-off rate; arc welding overhead rate was based on \$5 per hour plus \$0.62 per hour write-off rate.

Cost of Consumables and Tooling. Filler-metal costs were based on prices of \$15 per pound for 1/16-in.-diam Ti-6Al-4V wire and \$6 per pound for the maraging steel and for the HP 9-4-25 steel. The cost of shielding gas was assumed to be \$0.07 per cubic foot.

Tooling cost was estimated as \$2000 for the ¼-in. plate and \$3000 for the 1-in. plate, for both electron beam and arc welding, and was distributed over 200 cylinders (400 welds).

GAS WELDING

CONTENTS

Gas Welding Processes and Their Application to Steel

*By the ASM Committee on Gas Welding of Steel**

GAS WELDING, as it is dealt with in this article, is a manual process in which the metal surfaces to be joined are melted progressively by heat from a gas flame, with or without filler metal, and are caused to flow together and solidify without the application of pressure to the parts being joined. The most important source of heat for gas welding is the oxyacetylene welding torch. Other processes that make use of gas torches are discussed in separate articles in this volume.

The simplest and most frequently used gas welding system consists of compressed-gas cylinders, gas regulators, hoses, and a welding torch. Oxygen and fuel gas are stored in separate cylinders. The gas regulator attached to each cylinder (fuel gas or oxygen) controls the flow of gas from the cylinder to the flexible rubber hose that delivers the gas to a gland attached to the appropriate inlet on the welding torch. At the torch, the gas passes through an inlet control valve and into a mixing chamber; the mixed gases then pass through the welding tip and produce the flame at the exit end of the tip. This equipment can be mounted on and operated from a hand truck, or it can be a stationary installation. Filler metal, when needed, is provided by a welding rod that is melted progressively along with the surfaces to be joined.

The characteristics of the gas welding process discussed in this article are those pertaining mainly to gas welding as used for joining low-carbon steel. Gas welding for joining cast iron, and gas welding for hard facing a variety of metals, are dealt with in separate articles in this volume, and references are made where appropriate.

Capabilities, Advantages and Disadvantages

In gas welding, the welder has considerable control over the temperature of the metal in the weld zone. When the rate of heat input from the flame is properly coordinated with the speed of welding, the size, viscosity and surface tension of the weld puddle can be controlled, permitting the pressure of the flame to be used to aid in positioning and shaping the weld. The welder has control over filler-metal deposition rates, because the sources of heat and of filler metal are separate. Heat can be applied preferentially to the base metal or the filler metal, without removing either from the flame envelope. These capabilities make gas welding best suited for joining thin sheet metal, thin-wall tube, small pipe, and assemblies with poor fit-up, and for smoothing or repairing rough arc welds. Heavy sections can be joined by gas welding, but less economically than by arc welding.

The equipment is versatile, low-cost, self-sufficient, and usually portable. It can be used for preheating, postheating, welding, braze welding, and torch brazing, and it is readily converted to oxygen cutting. The process is well adapted to short production runs, field work, repairs and alterations.

For these reasons, gas welding is used in automotive and aircraft industries, in sheet-metal fabricating plants, and in the fabrication of industrial pipe. Many other industrial plants maintain gas welding equipment on a standby basis for maintenance work.

Metals That Can Be Gas Welded. Most ferrous and nonferrous metals can be gas welded, but an oxy-fuel gas mixture that will give the appropriate flame characteristics — flame temperature, heat-transfer intensity, and composition of flame atmosphere — must be selected. Flame characteristics of various fuel gases and oxy-fuel gas mixtures are discussed in the sections "Oxyacetylene Combustion" (page 569), "Oxy-Hydrogen Combustion" (page 570), and "Combustion of Natural Gas and Propane" (page 570).

Oxyacetylene supplies the heat intensity and flame atmosphere necessary for welding carbon steel, cast iron and other alloys of iron, copper alloys and nickel alloys. Aluminum and zinc alloys are also welded by the oxyacetylene process. Gas welding of steel is done almost exclusively with an oxyacetylene flame. Hydrogen, natural gas, propane and several proprietary processed gases are used as fuel gases in welding lower-melting metals, such as aluminum, magnesium, zinc, lead and some precious metals.

Except for lead, zinc and some precious metals, gas welding of nonferrous metals generally requires fluxes. This also applies to cast iron and stainless steel. In welding carbon steel, the gas flame adequately shields the weld, and no flux is required. Adjustment for correct flame atmosphere is important, but the absence of flux means that there is one less variable to control.

Eighteen examples, presented later in this article (Examples 506 to 523), describe some specific applications of gas welding to steel.

Metals unsuited to gas welding are the refractory metals (columbium, tantalum, molybdenum and tungsten) and the reactive metals, such as titanium and zirconium.

BABCOCK, Staff Engineer, Newark Laboratories, Linde Div., Union Carbide Corp.; W. S. BOEDECKER, Chief Engineer, Welding and Compressed Gas Equipment Div., Bastian-Blessing, Astro Controls, Inc.; E. A. DANIELS (retired), formerly Vice President, Victor Equipment Co.; JAMES A. HOWERY, Assistant Midwestern Manager, National Cylinder Gas Div., Chemetron Corp.; A. N. KUGLER, Consulting Engineer (formerly Chief Welding Engineer, Airco Welding Products Div., Air Reduction Co., Inc.); J. M. MCARTHUR, Manager of Metallurgical Service, Atlas Steels Co. Div., Rio Algom Mines Ltd.; HAROLD MENDENHALL, Smith Welding Equipment Div., Tescom Corp.; JOSEPH J. OKLADEK, Chief Design Engineer, Harris Calorific Co.; RALPH STAAL, formerly of Marquette Manufacturing Co., Inc.

Major Applications. Gas welding is particularly well-suited to the joining of thin carbon steel sheet, and carbon steel tube and pipe. The ability to control heat input, to avoid burn-through, to change direction quickly, and to bridge large gaps, when welding with this process, is highly advantageous in these applications. Carbon steel sheet, formed in a variety of shapes, often can be welded more economically by gas welding than by other processes. Gas welding is capable of joining small-diameter carbon steel pipe (up to about 3 in. in diameter) with resulting weld quality equal to competitive processes and sometimes with greater economy. Pipe with wall thickness up to ⅜ in. can be welded in a single pass.

Welder Skill. Gas welding requires skill in manipulating the welding rod and the torch flame. In depositing a weld, the welder uses both hands as he works at melting base metal and filler metal, controlling the weld puddle, and obtaining progressive solidification of filler metal of the correct bead shape.

Gases

Oxygen and acetylene are the principal gases used in gas welding. Oxygen supports combustion of the fuel gases. Acetylene supplies both the heat intensity and the atmosphere needed to weld steel. Hydrogen, natural gas, propane and proprietary gases are used only to a limited extent in gas welding.

Oxygen. Only by burning selected fuel gases in high-purity oxygen, in a high-velocity flame, can the high heat-transfer intensity required in gas welding be obtained. Oxygen is supplied for gas welding and cutting at a purity of 99.5% and higher. Because small percentages of contaminants have a noticeable effect on combustion efficiency, oxygen purity should not be below 99.5%. The most common impurities are argon, nitrogen and water vapor. Pure oxygen is so dry that water vapor is promptly absorbed from all forms of moisture, even traces of ice, in hoses and distribution lines.

When the consumption requirement is relatively small, the oxygen is supplied and stored as a compressed gas in standard steel cylinders under an initial pressure of 2200 psi. The most frequently used cylinder (see Fig. 1) has a capacity of 244 scf (standard cubic feet*). The gas is distributed for use under reduced pressure. Equipment for controlling the use of oxygen in gas welding operations is described in the following section on Equipment. When consumption of oxygen is somewhat greater, banks of cylinders are joined through a manifold header to permanent pipeline systems that terminate at various stations of use.

When oxygen consumption exceeds approximately twelve 244-scf cylinders per week, it may be more economical to obtain and store oxygen in liquid form. Liquid oxygen can be supplied in portable cylinders of 3000-scf capacity, or it can be delivered in bulk to a cryogenic tank where it is kept under a pressure of approximately 25 psi. Temperature during storage generally varies from −290 F (at time of delivery) to −180 F. To prevent too-rapid vaporization of the liquid oxygen, storage containers are built with an insulated double wall. To convert liquid oxygen to a gas having the desired rate of flow and the desired pressure, it is fed through a vaporizer. This is essentially a warming coil and pressure regulator. The gas is then piped to points of use.

The distribution and use of oxygen are covered by laws and safety regulations, designed to prevent injury to persons and damage to property. Users should be thoroughly familiar with the rules in the publications cited in the section on Safety, page 578.

*A standard cubic foot (scf) of gas is defined as equivalent to 1 cu ft of gas at 70 F and 1 atm (14.7 psi) pressure. This definition, which is used in the gas industry and some engineering practice, differs from the "standard temperature and pressure" of 0 C (32 F) and 1 atm pressure used in scientific work.

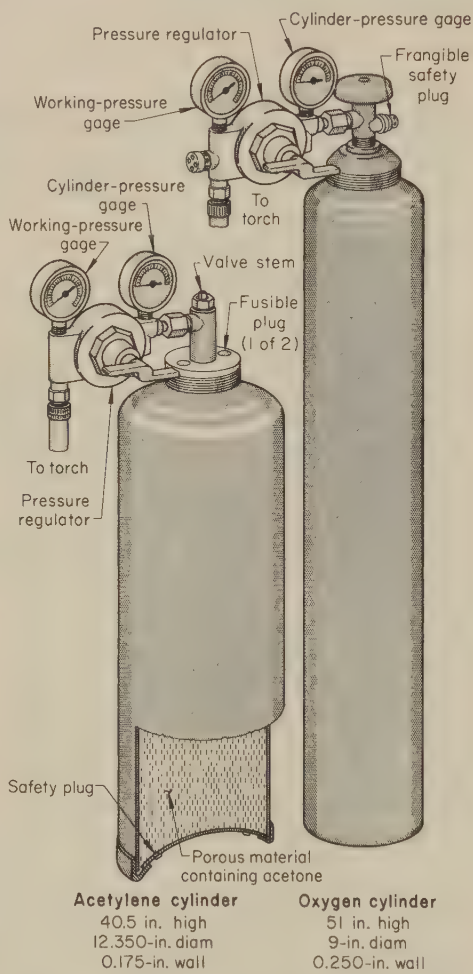

Fig. 1. Portable gas cylinders and regulators used in gas welding. The oxygen cylinder is the standard 244-scf-capacity cylinder, and the acetylene cylinder, the standard 275-scf-capacity cylinder.

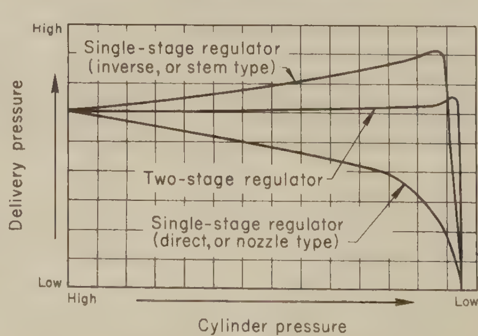

Fig. 2. Typical variation in delivery pressure for three kinds of pressure regulators

Acetylene is a hydrocarbon gas with the chemical formula C_2H_2. (See page 280 in Volume 4 of this Handbook for more information about this gas.)

Acetylene, when under pressure of 29.4 psi and above, is unstable, and a slight shock is likely to cause it to explode, even in the absence of oxygen or air. Therefore, safety rules for the use of acetylene and the handling of acetylene equipment are extremely important. Users and potential users should refer to the publications listed in the section on Safety, page 578.

Acetylene cannot be used safely at pressures greater than 15 psi. Therefore, acetylene generators for on-site gas production are constructed so that the gas will not be given off at pressures much greater than 15 psi. Commercially supplied portable cylinders are specially constructed (see Fig. 1) to store the acetylene under higher pressure. By dissolving the acetylene in liquid acetone, a cylinder such as that shown in Fig. 1 can be used safely to store about 275 scf of acetylene under a pressure of 250 psi. This pressure is reduced to no greater than 15 psi by the regulator (see Fig. 1) before the gas enters the hose or distribution line.

Acetylene cylinders must not be subjected to sudden shock and should be stored well away from any source of heat or sparks. The cylinders must be stored in an upright position to keep the acetone from escaping during use. Acetone will also be drawn off if acetylene is discharged at a rate exceeding 45 cu ft per hour.

Hydrogen is used chiefly for welding lower-melting metals, such as aluminum, magnesium and lead. It is not applicable to the welding of common thicknesses of steel sheet, because it results in a flame temperature that is too low to produce good fusion; it has, however, been used in welding of thin sheet, where its lower combustion intensity (about 60% of that of acetylene) is an advantage. It is used for brazing and, to some extent, for braze welding. Hydrogen is available in compressed-gas cylinders of various sizes.

Natural gas, propane and proprietary gases (each with oxygen) can be used to weld lower-melting metals, but their use in metal joining is usually limited to brazing. These gas mixtures are not applicable to the welding of steel, because when they are burned at temperatures high enough for welding, their flame atmospheres are excessively oxidizing; when ratios of oxygen to fuel gas are reduced to a carburizing condition, flame temperatures are too low.

Equipment

The principal function of gas welding equipment is to supply the oxy-fuel gas mixture to the welding tip at the correct rate of flow, exit velocity, and mixture ratio. The rate of gas flow affects the quantity of metal melted; the pressure and velocity affect the manipulation of the weld puddle and the rate of heating; the ratio of oxygen to

fuel gas determines the flame atmosphere, which must be chemically suited to the metal being welded, and the flame temperature. The following are important elements in a gas welding system: (*a*) gas-storage facilities, (*b*) pressure regulators, (*c*) hoses, (*d*) torch inlet control valves, (*e*) mixing chambers, and (*f*) welding tips.

Gas-Storage Equipment. Compressed-gas cylinders and storage tanks are used as on-site supply sources for gases. They are constructed under regulations of the Interstate Commerce Commission and, to some extent, are further regulated by federal, state and local laws. Cylinders are designed for specific gases and are not generally interchangeable. Sizes and threading of cylinder connections for oxygen, for example, differ from those for acetylene, hydrogen and other gases. It is extremely important that only the appropriate fittings be used for delivery of compressed gas. Users are cautioned not to tamper with valves or safety devices on cylinders.

When portable equipment is not required and gas consumption is large enough, permanent installations are constructed. Gases can be supplied from a variety of bulk-storage vessels, from manifolded gas cylinders, or from gas generators. The gases are then separately piped, at suitable pressures, to terminal stations, where they are drawn off through station regulators and used as in a portable setup.

Storage of oxygen and fuel gases is discussed in the section on Gases, on the facing page.

Pressure regulators deliver gas from a source of supply to the gas hose at a usable pressure and rate of flow. They are designed for specific gases and are not generally interchangeable. In Fig. 1, oxygen and acetylene pressure regulators of a type commonly used in gas welding are shown attached to their respective cylinders and hoses. In operation, gas enters the inlet side of the regulator at cylinder pressure and emerges from the outlet side at the desired working pressure. Regulators are made for various ranges of inlet and outlet pressure. They can be adjusted within their working-pressure range by turning an adjusting screw. This is done after the equipment has been completely assembled and the gas is free to flow from the welding tip. Although some regulators do not have gages and are preset to deliver at a specific and constant pressure, most are equipped with two pressure gages. The one on the outlet side permits the operator to read the adjusted working pressure; the one on the inlet side indicates the pressure in the cylinder.

Two basic kinds of regulators are used in gas welding: single-stage and two-stage. Both kinds are available with either direct or inverse actuation of the valve mechanism. Regulators with direct actuation are known also as positive or nozzle-type regulators; those with inverse actuation, as negative or stem-type. All single-stage regulators reduce cylinder pressure in one step. Not all single-stage regulators are safe to use on high-pressure cylinders. Pipeline regulators, made for lower pressures, must not be used on cylinders.

When adjusted for a desired working pressure, regulators continue to deliver gas, at the pressure shown on the outlet gage, within a fairly narrow range of deviation, as the cylinder pressure drops. The amount and direction of the deviation depend on the design of the regulator. The variation in delivered working pressure as cylinder pressure decreases is shown in Fig. 2 for three types of regulators. Both types of single-stage regulators require occasional adjustment as cylinder pressure drops. The more costly two-stage regulator supplies a more nearly constant working pressure until cylinder pressure nearly equals working pressure. On full oxygen cylinders exposed to low outdoor temperature in winter, two-stage regulators are more reliable than single-stage regulators. Temperature drop of expanding gas is less severe because pressure is reduced in two steps. Also, there is less chance for ice to form and clog regulator passages if water vapor is present.

Hoses. Flexible hoses permit the gas cylinders and regulators to be kept at a safe distance from the working area and allow the welder freedom of movement. They usually range from ⅛ to ½ in. in inside diameter (larger sizes are available for special applications) and are usually available in 25-ft lengths. If hoses are longer than 25 ft, it is sometimes advisable to use either the next-size larger hose or a length of larger-diameter hose with a short length of the normal size to connect to the welding torch to facilitate ease of movement. To ensure that oxygen hoses will be used only for oxygen, and acetylene hoses only for acetylene, oxygen hoses are generally green, with right-hand-threaded fittings; acetylene and other fuel-gas hoses are generally red, with left-hand-threaded fittings. Acetylene-hose fittings are grooved on the outside like the acetylene gland nut shown in Fig. 3 (lower left view).

Welding torches control the operating characteristics of the welding flame and enable manipulation of the flame during welding. The choice of size and style of torch depends on the type of work to be performed. Aircraft welding torches, for instance, are small and light, to permit ease of handling. Most styles of torches permit the attachment of one of several welding tips or a cutting head.

The general construction of an oxyacetylene welding torch is shown schematically in Fig. 3. The principal operating parts are inlet valves, mixing chamber and welding tip (or cutting attachment). By unscrewing the sleeve nut (Fig. 3), the welding tip and mixing-chamber assembly can be removed and replaced by units of different capacity. Torches of this type are used also for oxy-hydrogen welding. Torches for welding with natural gas, propane and proprietary gases may differ in details from the oxyacetylene torch.

Torch inlet valves provide the welder with two important controls. First, the pressure, velocity and flow in cubic feet per hour can be adjusted within the limits set by the pressure regulators and the practical requirements of the welding flame; and second, the ratio of oxygen to fuel gas can be varied. The ability of the oxyacetylene flame to produce the combustion intensity needed for welding, and at the same time to provide a suitable protective atmosphere for the weld metal, is largely a property of the fuel gas, but correct torch settings must be used (see the section on Selection of Tip-Orifice Size and Gas Pressure, next page).

Mixing chambers provide the intimate mixture of oxygen and fuel gas needed for rapid combustion, and also

influence gas flow. In Fig. 3, the mixing chamber is shown as part of an assembly with the welding tip. When the torch is assembled, the mixing chamber is seated on the torch-body gas ducts.

Two general types of mixing chambers are available: the equal-pressure type (also called positive-pressure and medium-pressure) and the injector type. In the equal-pressure type of mixing chamber, the gases are at essentially the same pressure and are mixed by directing the fuel gas into the oxygen stream, both traveling at essentially the same velocity. Detail A in Fig. 3 shows an equal-pressure mixing chamber assembled in position.

In the injector type of mixing chamber, low-pressure fuel gas is aspirated by directing it into a high-velocity stream of oxygen. A nozzle system based on the flow principles of the venturi tube is used. Injector-type torches are useful when fuel gases are supplied at pressures too low to produce a flame of adequate combustion intensity. There is usually no difficulty in supplying oxygen at desired pressure. By varying the design of the injector nozzle, different degrees of aspiration can be obtained. Designs for injector mixing chambers differ considerably in detail; one design is shown in cross section in Fig. 4.

Welding tips are replaceable nozzles that control gas flow by means of the diameter of the exit orifice. Tips of various orifice diameters are usually available for any welding torch. Orifice diameters are identified by drill-size number, by decimal size in inches, or by manufacturer's code number. Because code numbers of different manufacturers do not necessarily correspond, drill sizes or decimals are needed to compare the orifice size of different makes of tips. The performance of tips of equal size, at equal pressure-regulator settings, may differ, however, because of differences in torch and mixing-chamber designs.

Small-diameter tips produce small flames for welding thin sections; large-diameter tips are required for heavier work. Welding tips are made with a smooth bore at the exit end to ensure laminar flow and a uniform flame. The influence of bore configuration on the shape of flame is shown in Fig. 5. When foreign matter, such as carbon, dirt or weld spatter, enters the welding-tip orifice, it must be carefully removed. Specially designed dressing tools (known as tip cleaners) are available for this purpose.

Accessories essential to gas welding include an apparatus wrench made specifically for the several sizes of fittings used to assemble and disassemble the equipment, a friction lighter for igniting the torch, and welder's goggles and gloves.

Welder's goggles are covered by ANSI Standard Z49.1-67, "Safety in Welding and Cutting", which suggests the following lens shade numbers for use in gas welding of steel:

Steel thickness	Shade No.
Up to ⅛ in.	4 or 5
⅛ to ½ in.	5 or 6
Over ½ in.	6 to 8

It is essential for general gas welding that the goggles have side shields.

Selection of Tip-Orifice Size and Gas Pressure

Torch manufacturers supply charts that give tip-orifice size and the approximate gas pressures to be used for welding different thicknesses of metal. Table 1 presents the data from a typical chart showing these relationships. These pressures are approximate and they must be adjusted by the welder to obtain a flame that has the correct ratio of oxygen to fuel gas and other characteristics that may be required for the specific torch or job conditions or are peculiar to his style of work. These adjustments are described in the sections on Flame Adjustment and Oxyacetylene Combustion, below.

Tip size number and drill size are not precise means of comparing tips, because there are significant differences between a tip of the same dimensions when operated under positive pressure and when operated under injector pressure. The only valid basis of comparison is the volume of fuel passing through the tip in a unit of time. Most tips will operate within a range, usually recorded as cubic feet of fuel per hour.

Table 2 compares the tip-orifice diameters and gas pressures used in the production examples described in this article with those shown in Table 1. There are several reasons for the differences: (*a*) the design and performance of regulators, torches, mixing chambers and tips differ from one manufacturer to another; (*b*) a welder will adjust the pressures to suit the particular job conditions; and (*c*) some welders make choices based on personal preference or habit, such as setting the gas regulators at pressures higher than recommended and then throttling down the gases at the torch. It may be claimed that this practice increases welding speed (see Example 512), but it is not a safe practice. It contributes to flashbacks, which are extremely dangerous, and also to backfires. Serious accidents involving flashbacks have occurred when welders have deviated from recommended practice.

Flame Adjustment

Different welding atmospheres and flame temperatures can be produced by varying the relative amounts of oxygen and fuel gas in the gas flowing to the tip of the torch. Usually a welder makes the appropriate adjustments in gas flow on the basis of the appearance of the flame (except in oxy-hydrogen gas welding).

The sequence for setting up a positive-pressure welding outfit is:

1 Individually crack each cylinder valve to blow out foreign matter. Make sure vented gases are safely dispersed. Wipe out cylinder-valve outlet with a clean, lint-free cloth.
2 Attach the oxygen regulator to the oxygen cylinder or manifold.
3 Attach the acetylene (or fuel-gas) regulator to the fuel cylinder or source.
4 Connect the welding hose to the regulators and the welding torch.
5 Individually purge the oxygen line while the acetylene line is closed and the acetylene line while the oxygen line is closed. Vent gases safely.
6 Set the oxygen and fuel-gas regulators to the recommended working pressure with appropriate torch valve open.
7 Open the acetylene (or fuel-gas) inlet valve and light the welding torch, using a spark lighter.
8 Open the oxygen inlet valve and adjust the flame, using both inlet valves.

For injector-type equipment, the sequence and method of setting up will differ from that given above, because high-pressure oxygen aspirates low-pressure acetylene into the torch. There are sufficient differences among brands of equipment so that the user is urged to follow the manufacturer's instructions for exact details in setting up.

The following three sections describe the combustion of acetylene, hydrogen, and natural gas and propane fuel gases with oxygen.

Oxyacetylene Combustion

As the acetylene-oxygen mixture burns from the tip of the welding torch, it displays several zones of combustion, which are clearly recognizable. The over-all chemical equation for the complete combustion of acetylene is:

$$2C_2H_2 + 5O_2 \rightarrow 4CO_2 + 2H_2O$$

Combustion takes place in two stages. The first stage:

$$2C_2H_2 + 2O_2 \rightarrow 4CO + 2H_2$$

uses the oxygen supplied from the cylinder and available in the oxyacetylene mixture, and the reaction can be seen as the small inner cone of the flame. The highest temperature is at the point of this cone. The second stage:

$$4CO + 2H_2 + 3O_2 \rightarrow 4CO_2 + 2H_2O$$

uses the oxygen supplied from the air surrounding the flame. This combustion zone constitutes the outer envelope of the flame.

It may be seen from the above that about two-fifths of the oxygen necessary for the complete combustion of acetylene comes from the oxygen cylinder; the remainder comes from the air. Because of the need for supplemental oxygen from the atmosphere, the acetylene-oxygen flame cannot be used inside of tubes or structures subject to oxygen depletion from gas welding. By varying the relative amounts of acetylene and oxygen in the gas mixture in the torch, a welder can produce different flame atmospheres and temperatures.

The second equation shows that in the first stage, when equal amounts of oxygen and acetylene are burning, neither excess acetylene nor excess oxygen will be present at the high-temperature tip of the inner cone. For this reason, the flame is called neutral, and the gas mixture is often described as an acetylene-to-oxygen ratio of 1 to 1 (or simply as an equal ratio). The condition of the flame is important, because the inner cone is held close to, but not touching, the work metal. If excess oxygen is present, the molten metal will foam and spark and brittle oxides may form in the weld metal. If acetylene is present in sufficient excess (indicated by an acetylene feather greater than about three times the length of the inner cone), carbon will enter the metal; some of the carbon will form carbides and some will burn, causing gas and porosity in the solidified weld metal. In austenitic stainless steels, carbides formed in this manner aggravate susceptibility to intergranular corrosion. In welding steel, the flame should be as nearly neutral as possible, but a perfectly neutral flame is difficult to recognize and it is therefore usual to employ a flame containing a slight excess of acetylene.

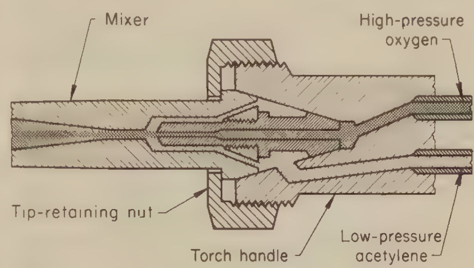

Fig. 4. An injector mixing chamber for a gas welding torch (section taken through joint between welding tip and torch handle)

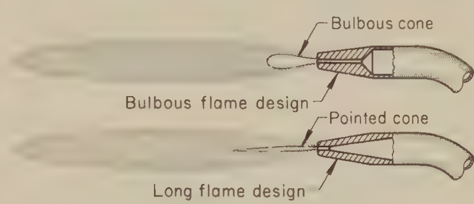

Fig. 5. Shapes of inner cones of oxyacetylene welding flames, produced by welding tips with two different bore configurations. Varying the transition taper produces cone shapes intermediate between those shown.

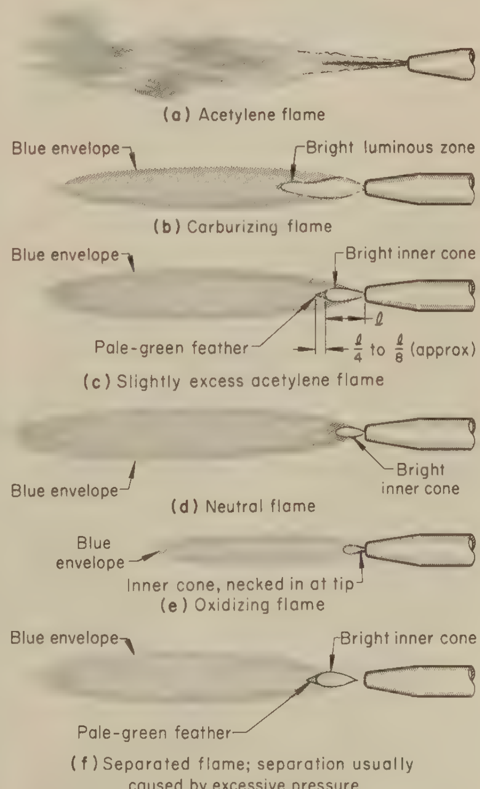

Fig. 6. (a) to (e) *Conditions visible during adjustment of an oxyacetylene flame;* (f) *separated flame caused by excessive pressure*

A neutral flame is obtained by observing the size and color of the combustion zones in the flame as the oxygen-to-acetylene ratio is changed by adjusting the torch inlet valves. Figure 6 shows five typical flame conditions that appear as oxygen flow is increased from zero to excess oxygen, and a separated flame condition that results from excessive gas pressure.

Acetylene Flame. When acetylene alone is burned in air, it produces a flame that varies in color from yellow near the torch tip to orange-red at the extremity, with soot particles floating off into the air. This is not a working flame. This flame is shown in Fig. 6(a).

Carburizing Flame. As the oxygen valve in the torch is progressively opened and the ratio of oxygen to acetylene increases, the flame becomes generally luminous. Then, the luminous portion contracts toward the welding tip, forming a distinct bright zone within a blue outer envelope, as shown in Fig. 6(b). This is a carburizing flame because it has a large excess of acetylene. It is sometimes described as a "soft" flame because it has very little force. It has a relatively low temperature and is used in silver brazing and soldering, and in the welding of lead.

Reducing Flame. As more oxygen is introduced, the bright zone of the flame contracts farther and is seen to consist of two parts: a bright inner cone and a pale-green streamer or "feather" trailing off its end into the blue envelope. The streamer or feather is due to a slight excess of acetylene. It disappears as the oxygen-to-acetylene ratio approaches 1 to 1. In Fig. 6(c), the feather is shown adjusted to about one-quarter the length of the inner cone. For the welding of steel, the length of the feather should be about one-eighth to one-quarter, but never more than one-half, the length of the inner cone. The flame is properly described as a slightly excess acetylene or reducing flame. It should not be called a carburizing flame because it will not carburize the metal, but it will ensure the absence of the oxidizing condition. It is frequently used for welding with low-alloy steel rods. The flame temperature at the tip of the inner cone is about 5300 to 5500 F.

In the neutral flame shown in Fig. 6(d), the oxygen-to-acetylene ratio is 1 to 1 (more accurately, 1.1 to 1) and the temperature at the tip of the inner cone is probably above 5500 F. As pointed out earlier, it is difficult to make the precise adjustment of the inlet valves that results in a neutral flame, particularly in sunlight, because the oxidizing flame is of similar appearance. The neutral flame is ideal for the welding of steel and when

the presence of carbon must be strictly avoided; when the oxidizing condition is unacceptable, as in welding stainless steel, the use of a neutral flame is essential to good results.

An oxidizing flame is shown in Fig. 6(e). The adjustment of the inlet valves for this flame is also difficult, because it cannot be made on the basis of luminosity. The best indication that the oxidizing condition has been obtained is when the flame tends to neck in at the juncture of the inner cone and the tip of the torch. When the flame is adjusted to be extremely oxidizing, it may also produce a hissing sound. An oxidizing flame should never be used in welding steel. Its only use is in welding copper and certain copper-base alloys, and the flame should be just sufficiently rich in oxygen to ensure that a film of oxide slag will form over the weld to provide shielding for the weld puddle. With oxygen-to-acetylene ratios of about 1¾ to 1, flame temperature will exceed 6000 F.

Separated Flame. When gas pressure is too high for the size of the tip used, the flame will separate from the tip (see Fig. 6f) and may even blow out. This is an unusable flame condition and must be avoided. Another cause of this condition is a clogged tip orifice.

Shape of Flame Cone. The design of the welding tip largely determines the shape of the inner cone of the oxyacetylene flame (see Fig. 5); however, as the amount of oxygen used in the gas mixture is increased, the shape of the cone becomes more pointed.

Both bulbous and pointed cones are equally satisfactory and will produce sound welds. The flame with the bulbous inner cone is generally preferred for welding in deep grooves in heavy sections. The flame with the long, pointed inner cone is softer and is preferred for the welding of thin sheet and aircraft assemblies. Some welders prefer the long, pointed inner cone for joining pipe because that shape facilitates penetration and fusion for the root pass in single-V grooves.

Oxy-Hydrogen Combustion

Complete combustion of hydrogen requires an oxygen-to-hydrogen ratio of 1 to 2, as can be seen from the following equation:

$$2H_2 + O_2 \rightarrow 2H_2O$$

This gas mixture produces a strongly oxidizing flame having a temperature of about 5000 F.

It is impossible to obtain a neutral oxy-hydrogen flame by the visual methods of flame adjustment described earlier for the oxyacetylene flame. The oxy-hydrogen flame itself is scarcely visible, and there are no combustion zones such as are typical of the hydrocarbon gases. To avoid an oxidizing flame, the pressure regulators must be set to provide an assured excess of hydrogen. The flame is then reducing but not carburizing, because there is no carbon, and the temperature is several hundred degrees lower than that of the neutral flame. Metering flow-type regulators permit establishing the desired ratio of hydrogen to

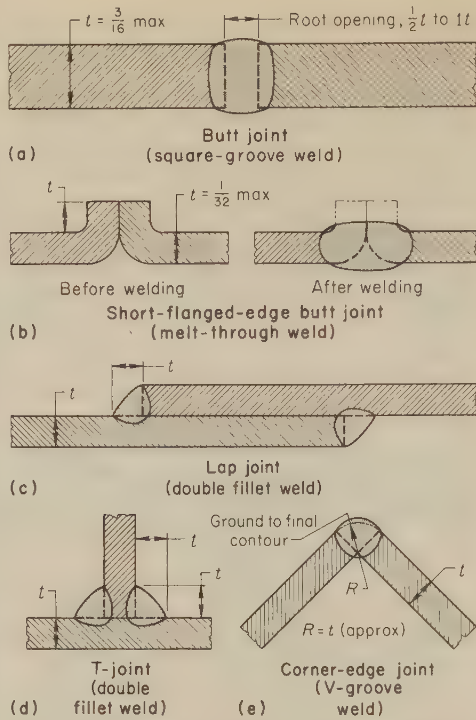

Fig. 7. Typical joints and corresponding single-pass welds used in gas welding of thin sheet

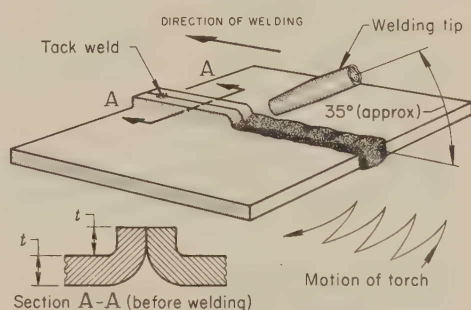

Fig. 8. Gas welding technique for making a short-flanged-edge butt joint in thin sheet (up to about 1/32 in. thick)

oxygen, usually 4 to 1. The oxy-hydrogen flame is useful for welding and brazing aluminum alloys.

Water welding is the misnomer given to an oxy-hydrogen process in which oxygen and hydrogen, generated from water in a small electrolytic cell supplied from the water mains, are produced in the exact quantities needed for complete combustion. The gases are supplied to a torch provided with a welding tip about the size of a hypodermic needle. The flame is oxidizing, but a reducing flame can be obtained by passing the gases over alcohol. The flame produced by recombining the gases from an electrolytic cell is used for joining small parts, such as electronic leads and connections, and in the manufacture of jewelry.

Combustion of Natural Gas and Propane

Complete combustion of natural gas (methane) and propane is shown, respectively, by the following equations:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$
$$C_3H_8 + 5O_2 \rightarrow 3CO_2 + 4H_2O$$

When the flame temperature is high enough to weld steel, the flame atmosphere is excessively oxidizing, but when the ratio of oxygen to fuel gas is decreased to produce a carburizing condition, flame temperature is too low.

Welding Rods

Filler metal for gas welding low-carbon steel is available in the form of cold drawn steel rods 36 in. long and 1/16 to ¼ in. in diameter. Welding rods for gas welding other metals are supplied in various lengths, depending on whether they are wrought or cast.

Specifications. Steel welding rods have been standardized in the AWS specification A5.2, "Iron and Steel Gas Welding Rods". The 1969 revision of this specification shows three classifications of welding rods, based on the minimum tensile strength of all-weld-metal and transverse-weld test specimens, as in the table that follows:

AWS classification	Minimum tensile strength, psi	Minimum elong in 4D, %(a)
RG65	67,000(b)	16
RG60	60,000(b)	20
RG45	45,000(c)	...

(a) Elongation in approximately 1 in. (b) All-weld-metal test specimens, 0.252 ± 0.005 in. in diameter; as-welded condition. (c) Tension tests based on transverse-weld test specimens, 2 by ⅜ in. in cross section; as-welded.

The specification covers the chemical composition of the welding rods only to the extent of limiting sulfur and phosphorus to 0.040% max, and aluminum, if present, to 0.02% max. Therefore, welding rods of different manufacturers may vary appreciably in chemical composition. The uses of these three rods are discussed later in this section.

Rods for gas welding of steel have no flux covering and out-of-position welding depends solely on welder skill. Some techniques employed are described in the following section. In the absence of flux coverings, weld-metal properties depend on chemical composition of the welding rod, control of the welding atmosphere, and the techniques used to provide for mixing of base metal and filler metal.

Deposition Techniques. The mechanical properties specified for the RG65, RG60 and RG45 rods are obtained by welding in a neutral to slightly excess acetylene atmosphere. The technique for obtaining this atmosphere is described in the section on Oxyacetylene Combustion in this article.

Forehand and backhand welding techniques can be used in gas welding with rods. Although excessive agitation of the weld puddle is generally undesirable, controlled agitation can be used to aid in the mixing of base metal and filler metal and thereby to secure the desired weld-metal properties.

Weld-Metal Strengthening. The ability to control the properties of the weld by mixing base metal and filler metal means that the choice of welding rod can influence weld strength to a considerable extent, as described in the following: Fully reinforced welds in thin-wall tubes of 4130 welded with an RG45 rod consistently showed tensile strengths of 90,000 to 100,000 psi.

When the welds were made with RG60 rods, the strengths increased to 100,000 to 125,000 psi, and with RG65 rods, strengths as high as 145,000 psi were attained when the joint was heat treated after welding.

Class RG65 welding rods have a low-alloy steel composition and are used for the gas welding of carbon and low-alloy steels that have strengths of 65,000 to 75,000 psi. They are used on sheet, plate, tube and pipe. These rods give the highest strengths in welding 4130, 4340 and 8630 alloy steels when the mixing principle described above is used. The end use has a marked effect on selection of filler metal. For instance, if the base metal was selected to meet a specific corrosion or heat-resisting application, the filler metal should be of similar composition. On the other hand, if a room-temperature mechanical property is the primary requirement, the strength and ductility of the filler metal should be made the basis of selection.

Class RG60 welding rods are probably the most widely used. They are generally of low-alloy steel and are preferred for the gas welding of carbon and low-alloy steels in the tensile-strength range of 50,000 to 65,000 psi. Class RG60 rods are most commonly used for such purposes as welding carbon steel pipes for power plants.

Class RG45 welding rods have a simple low-carbon steel composition. These rods can be used for gas welding of carbon and low-alloy steels.

Fluxes

No flux is used in the gas welding of steel. Fluxes *are* used in the gas welding of cast iron, stainless steel, and most nonferrous metals other than lead, zinc and some precious metals.

Joint Design and Edge Preparation

Joints used in gas welding comprise butt, lap, edge, T and corner joints. Either fillet or groove welds are used, depending on the workpiece and on strength requirements.

Sheet. Five types of joints commonly used for single-pass gas welding of low-carbon steel sheet are shown in Fig. 7. For gas welding, beveling of joint edges is not needed in sheet up to 3/16 in. thick, and if good shearing practice has been followed in trimming sheets to size, no special edge preparation is required. However, edges must be free of rust, dirt, oil, and grease.

Square-groove butt joints (Fig. 7a) can be single-pass welded from one side in sheet up to approximately 3/16 in. thick. Complete-penetration welds, properly made, will develop the same strength in low-carbon steel as the members joined.

Short-Flanged-Edge Butt Joints. For making butt joints in sheet up to about 3/32 in. thick, it is often advantageous to use a short flanged edge (Fig. 7b). The weld is called a melt-through weld because the flanges are melted down to form the butt joint. Filler metal is not required. The oscillating technique for melting down the flanges is shown in Fig. 8. The flanges keep the sheets in flat alignment.

Although the sheet has to undergo a special flanging operation, this joint is practical on long production runs when filler-metal deposition and melt-through are difficult to control. High welding speeds can be attained. Sheet thicknesses are limited to approximately 1/32 in. because short flanges are difficult to bend in heavier material.

In other flanged-edge joints, the weld is deposited on the edges, and the flanges retain their structural identity.

Without appropriate support of the adjacent sheet, long sections of thin material cannot be welded without buckling and distortion. The amount of distortion that results from the expansion during welding and contraction during cooling of the welded sheet-metal section or structure is proportional to the amount of heat applied to the metal as well as to its inherent stiffness and rigidity. Jigs and fixtures are essential to counteract the adverse effects of welding heat. Figure 9(a) shows the elements of a jig commonly used for making butt or flange welds in thin sheet.

Lap and T-joints, as shown in Fig. 7(c) and (d), are single or double fillet welded, depending on strength requirements. A single fillet weld is not recommended if the joint is likely to open under service loads. The amount of overlap in lap joints varies with design requirements and sheet thickness. For double-welded lap joints, a minimum overlap of approximately 1 in. is usually adequate for sheet.

The size of fillet weld (size is defined to mean the leg length of the largest isosceles right triangle that can be inscribed within the fillet-weld cross section) is generally equal to the thickness of the sheet, because this size of weld is easily produced in a single pass and has a good appearance. Lap and T-joints are seldom used where the full strength of joined sections is needed.

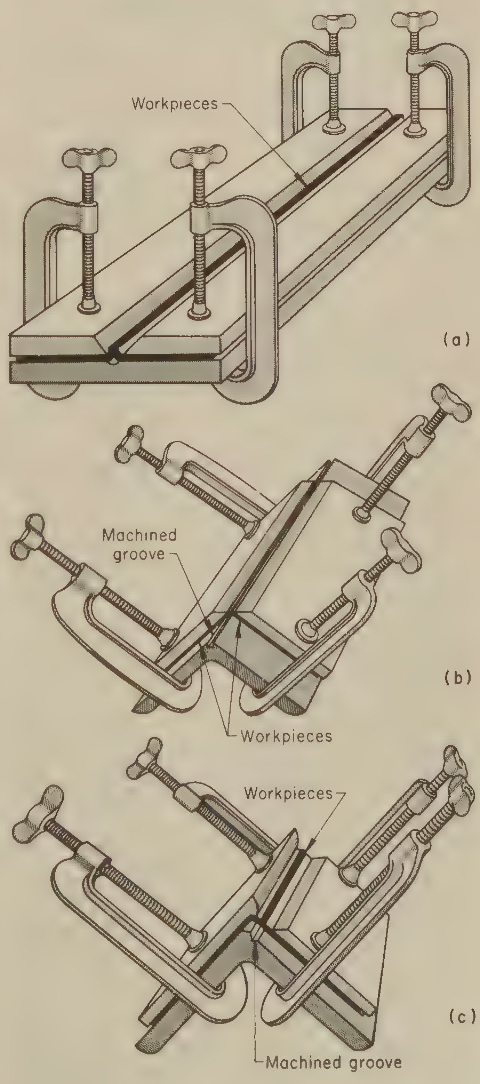

Fig. 9. Jigs used with thin sheet to help maintain flatness and minimize distortion

Both lap and T-joints are somewhat more difficult to weld in thin sections than in thick sections because of the danger of melt-through when a welder attempts to penetrate to the root of the joint.

Corner joints of the type shown in Fig. 7(e) are used in thin material, mainly because of their simplicity and low cost, and because skillful gas welding can produce a weld of good external appearance in a single pass. The usual method employed is to deposit an excess of filler metal in a single pass and then to finish the weld by grinding to a radius approximately equal to the sheet thickness, as shown in Fig. 7(e).

To improve internal appearance and to provide added strength, an internal pass or removable backing is needed. Square corner joints in thin material can be made with good appearance and strength and with little or no distortion by using a jig constructed as shown in Fig. 9(b). A recess is machined or ground in the corner of the backing plate to provide for root reinforcement of the V-groove weld.

When parts with rounded corner joints are designed in thin sheet, consideration should be given to bending rather than joining the corners. Joints next to the corners can be made by butt welding in a jig constructed as shown in Fig. 9(c). Note the use of a recess in the backing member to provide for root reinforcement of the weld.

Plate. Butt, lap, T and corner joints are gas welded in steel plate (3/16 in. and thicker). Butt joints welded from one side only require beveled edges in thicknesses over 3/16 in. However, complete-penetration welds are made in square-groove butt joints up to 5/16 in. thick by single-pass welding from both sides and back gouging the first, or root, pass. Joints are considered to be only partially penetrated when welded from both sides without back gouging the first, or root, pass.

Lap and T-joints can be gas welded in any plate thickness, using single-pass or multiple-pass fillet welds. When these joints are in heavy plate, the size of the fillet welds should be held to a suitable fraction of section thickness to avoid overwelding, which is costly. Corner joints also can be gas welded in any thickness, but in heavy sections this joint design produces an unsatisfactory stress distribution in the weld. One alternative is to extend one of the plates past the other to form a T-joint, which can be double fillet welded; another is to reinforce the corner joint with structural sections.

It should be noted, with respect to heavy plate, that gas welding is at a disadvantage compared to arc welding, because it is slower. Gas welding is not widely used on heavy plate.

Fillet welds have several advantages and disadvantages, compared with groove welds. No edge preparation in the form of chamfering or beveling of joint edges is required. If the weld serves mainly to hold structural members together, or if forces transmitted by the weld are low, fillet welds can be relatively small and economical. If welds are required to develop the full strength, or a high percentage of full strength, of the members joined, fillet welds become more bulky and more costly as section thickness increases.

Groove welds are used in butt joints and can be used in lap, T and corner joints as an alternative to fillet welds. In low-carbon steel, complete-penetration groove welds, properly made, will develop strength equal to the strength of the members joined.

Typical grooves used for gas welding of butt, T and corner joints in steel plate 3⁄16 in. or more thick are shown in Fig. 10. Grooves for gas welding are the same as those for arc welding, except that groove angles are usually larger to permit manipulation of torch and rod, and to provide good access to the root for full penetration.

The V-grooves and single-U groove shown in Fig. 10(a), (b) and (c) are for complete-penetration welds in butt joints. The bevel grooves and J-groove shown in Fig. 10(d), (e) and (f) are similarly used in butt, T and corner joints. Section thickness increases from (a) to (c) and (d) to (f) in Fig. 10. The purpose of changing groove design as section thickness increases is to obtain the least cross-sectional area of weld, and thus to reduce welding cost. The dimensions shown in this figure are typical rather than mandatory; reasonable variations are permissible. A double-U groove and a double-J groove are not shown because they are used for very thick sections, and gas welding of such sections is rare.

The edges of joints intended for groove welds can be prepared by gas cutting, plasma-arc cutting, milling, shaping, planing or turning, depending on the shape and size of the part, and other conditions. Only machine-guided torches should be used when beveling is done by gas cutting.

Pipe. Most pipe welding is done on circumferential butt joints. Wall thicknesses up to about 3⁄8 in., can usually be welded in a single pass. A greater wall thickness requires more than one pass. Grooves must be large enough to permit manipulation of the torch and to facilitate adequate root penetration. The root pass must be made with care and skill to obtain complete penetration and smooth fusion at the inner surface of the pipe. Joints for pipe of up to about 1⅛-in. wall thickness are usually made with single-V grooves. In thicker-wall pipe, the single-U groove may be preferred.

On walls up to and including ⅛ in. thick, a 30° bevel (60° included angle) can be made by grinding the pipe ends. When wall thickness is greater than ⅛ in., the pipe ends are usually beveled to a 37½° angle, which provides a 75° groove angle. These limitations are not mandatory and can be varied somewhat. Smaller grooves are sometimes used by experienced welders.

Bevels can be cut by chipping, grinding, turning or gas cutting. Beveling machines using gas cutting torches or cutting tools are used when large quantities of pipe are involved. Manual gas cutting is used when some form of guided cutting is not available, but manually gas-cut edges are likely to be rough and may have adhering slag. A light grinding operation is often needed to clean the beveled edges and remove gouges before welding.

Elbows, return bends, T's, crosses, Y-branches, reducing sections, end caps and flanges that are to be welded to small-diameter pipe are usually obtained as forged fittings prepared for circumferential butt welding. These fittings have been forged with their ends beveled to an angle of 30° to 37½°, which on fit-up provides welding grooves of 60° to 75° included angle.

When joints must be made in intersecting pipes that are not coaxial, or when pipe diameters differ, the angle of bevel must suit the contour at the intersection.

Thin-Wall Tube. Joints in thin-wall tube vary from simple circumferential butt or lap joints to any configuration resulting from the intersection of a tube with another shape. Whereas pipe is usually beveled, thin-wall tubing (like thin sheet) requires no particular edge preparation. Standard pipe fittings do not generally fit tubes.

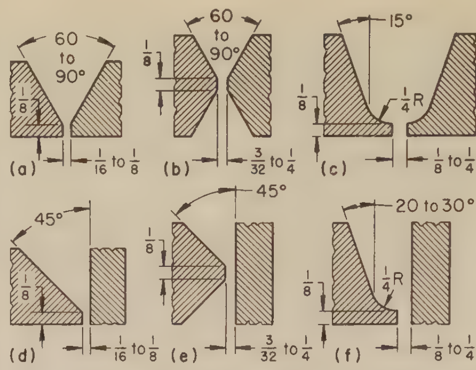

Fig. 10. Typical grooves used in gas welding plate 3⁄16 in. or more thick

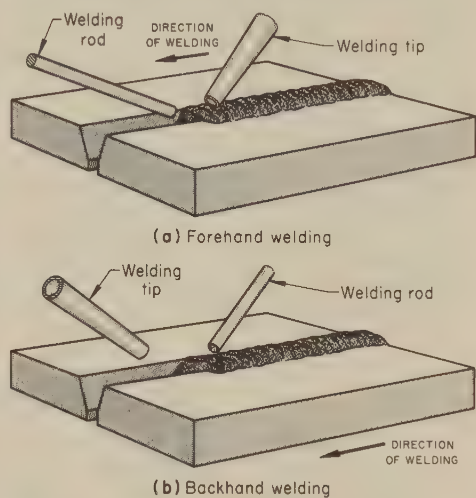

Fig. 11. Two basic techniques for manipulation of the welding tip and the welding rod in gas welding. See text at right for discussion of relative merits of the two.

Several typical joints in thin-wall tube are discussed in Examples 513 to 517, and are shown in Fig. 19.

In repair work and alterations, edge preparation for welding generally involves cutting a V-groove to expose clean metal down to the root of the joint. The groove must be large enough so that there is room for manipulation of the torch and of the welding rod.

In weld repairing of parts that have cracked, the crack should be fully dressed out. Metal can be removed by chipping, grinding, machining, arc-air gouging, or oxyacetylene gouging. For gas welding, oxyacetylene gouging is a convenient method because a cutting torch is generally available and only a special gouging tip is needed.

An advantage in using oxyacetylene gouging for dressing cracks is that the crack remains visible until it is completely removed. Grinding may result in a fine crack being smeared over. Chipping also is likely to cover the crack. The disadvantage in using oxyacetylene gouging is that the heat input may cause the crack to propagate, through differential expansion in the workpiece. The risk is especially great if some of the stresses that caused the crack are still present, or if brittle material such as cast iron is being gouged. Oxyacetylene gouging is not readily accomplished on cast iron.

Cleaning. Cleanness of the joint is a prerequisite for gas welding. Rust, scale, dirt, grease, oil, paint and slag must be removed from the joint areas. The soundness of the weld metal depends in large part on the care exercised in cleaning.

Techniques

Forehand and backhand techniques are used in gas welding, and the usual welding positions (flat, horizontal, vertical and overhead) are employed. Techniques vary to some extent for different joint thicknesses, welding positions and welder preferences.

In forehand welding, illustrated in Fig. 11(a), the flame is pointed away from the completed weld, in the direction of welding, with the torch being held at about 45° to the workpiece. The welding rod is held at an angle of about 40° to the workpiece, with the flame being between the tip of the rod and the weld. The inner cone of the flame is held close to, but not touching, the work. The torch is moved from side to side so that the flame heats the welding rod, the edges to be welded, ahead of the flame, and the weld metal. The rod may be oscillated in a direction counter to the side-to-side movement of the torch. Both the welding-rod tip and the weld puddle should be kept under the shielding influence of the flame.

The forehand technique requires careful manipulation to guard against excessive melting of the base metal, which results in considerable mixing of base metal and filler metal. The influence of the base metal on the properties of the weld metal can be very great.

In backhand welding, illustrated in Fig. 11(b), the flame is pointed toward the completed weld. The tip of the welding rod is held between the flame and the weld, at an angle of about 40° to the workpiece, and the torch, at about 50° to the workpiece. Rod and torch are usually oscillated slightly in opposite directions. Because there is usually less side-to-side movement of the flame and less melting of the joint edges, a backhand weld is more likely to retain the properties of filler metal without alteration by the base metal. There is also less agitation of the weld puddle, better protection of the weld metal by the flame, and slower cooling of the weld than in forehand welding.

Backhand welding is often preferred to forehand welding for joints in metal thick enough to require beveled edges. Smaller grooves can be used because the flame need not be moved around the rod to melt the edges of the groove. Proponents of this technique believe that it saves time, filler metal, oxygen and acetylene. To ensure against cold laps and oxide inclusions at the weld root, the flame should be directed primarily at the heavier and continuous section of base metal when making a fillet weld with the backhand technique, as shown in Fig. 12.

Flat and Horizontal Positions. Gas welding in the flat and horizontal positions presents few problems. However, when root openings must be large because joint thickness is large, the backhand technique is preferred. If the forehand technique is used, it is necessary to work the molten puddle from side to side, as well as forward, with the aid of the flame.

Vertical and Overhead Positions. In vertical and overhead welding, careful control over heat input is needed to keep the viscosity of the weld puddle high enough so that the weld metal does not drip. In addition, the force of the flame must be directed so as to ensure that the weld puddle solidifies in the correct position. The keyholing technique for vertical and overhead welding of thin sheet is described in the next section.

Welding of Thin Sheet

Techniques used in gas welding of thin sheet depend on joint design and welding position, as well as on the style of manipulation used by the welder. Although forehand and backhand techniques can be used for gas welding thin sheet, forehand welding is often preferred because the flame points away from the completed weld and therefore there is less heat buildup and less risk of distortion and melt-through. Proponents of this technique believe also that thin sections can be forehand welded faster in the flat or horizontal position because the flame forces the weld metal to flow in the direction of welding. In Fig. 8, the short-flanged-edge joint is shown being welded with the torch pointed in the forehand direction.

For welding sheet up to ⅛ in. thick in the vertical position, the keyholing technique can be used. This technique requires that the weld be started at the bottom of the joint by building up a shelf, and then progressing upward with a side-to-side motion of the flame as in flat-position welding. When the manipulations of the flame and welding rod are properly coordinated, the effect known as keyholing will occur, as shown in Fig. 13. The same effect can be achieved in overhead welding, but in this position the torch is held perpendicular to the weld puddle and the welding rod is held at about 45° to the weld, leading the flame.

Assemblies of steel sheet less than ⅛ in. thick are often made by gas welding. The risk of melt-through is small because the welder has considerable control over the temperature in the weld zone. However, because of the relatively long welding time involved, gas welding does not permit critical control over total heat input and therefore distortion can occur when long, continuous welds are made in large, flat thin sheets. For this reason, gas welding of thin sections is best done on small parts, where welds can be short, or on sections that have been strengthened by forming. Welding fixtures are often used to prevent distortion and to maintain alignment of joint edges.

The problems arising from difficulties in heat control in joining of thin sections by gas welding are sometimes solved by using other metal-joining processes, such as short-circuiting gas metal-arc welding, pulsed-arc welding, gas tungsten-arc welding, plasma-arc welding, electron beam welding, ultrasonic welding, resistance welding, brazing, and braze welding. These processes are treated in other articles in this volume.

Products that are made by gas welding of thin sheet usually employ material in the thickness range of 0.0239 in. (24 gage) to 0.1196 in. (11 gage). Typical items include truck bodies, furniture, office equipment, utensils, enclosures, and refrigeration equipment. In the three examples that follow, gas welding was selected rather than arc welding to minimize the likelihood of melt-through of the relatively thin (18 and 20-gage) steel sheet used in these applications.

Table 3. Conditions Employed for Gas Welding of Automotive Body Parts From Thin Sheet Steel (Examples 506, 507 and 508)

Condition	Example 506 (Cover assembly)	Example 507 (Truck-body subassembly)	Example 508 (Truck-cab assembly)

Examples 506, 507 and 508. Gas Welding of Thin Low-Carbon Steel Sheet

Example 506 — Cover Assembly (Table 3). A cover assembly, in the shape of an open-top box 10 by 12 in. by 3½ in. deep and having a flanged lip, was formed from a single sheet of steel by bending the four sides and the lip. The 3½-in.-deep corner joints were then gas welded inside and out. Specifications called for 18-gage (0.048-in.) 1008 to 1020 steel, cold rolled, with a temper of 3 to 5 (quarter hard to dead soft).

Gas welding was used for closing the four corner joints because experience with arc welding had shown that melt-through was likely to occur. Production schedules depended on speed and reliability. Welding conditions are given in Table 3.

The formed cover assembly was clamped in a welding fixture and welded in the vertical position. Very little warpage occurred and there was no melt-through.

Example 507 — Truck-Body Subassembly (Table 3). A truck-body subassembly required joining a 20-gage (0.036-in.) instrument-panel frame to an 18-gage (0.048-in.) windshield frame. Material specifications called for 1008 to 1015 cold rolled steel of drawing quality, with a temper range of 3 to 5 (quarter hard to dead soft). Seven short lap welds were required to join the parts. A welding fixture held the parts in close alignment so no tack welding was required during fit-up. Various welding positions were used. Because fast, accurate placement of the welds, without melt-through, was required, gas welding was used in preference to arc welding. Welding conditions are shown in Table 3. There was no melt-through, warpage was negligible, and no special problems were encountered.

Example 508 — Truck-Cab Assembly (Table 3). Both lap and butt joints were used for joining sections of a truck-cab assembly. The stampings to be joined were made of 18-gage (0.048-in.) 1008 to 1015 cold rolled steel of drawing quality. The spacing between the parts to be joined was often found to be inconveniently large. Nine welds, made in different positions under good-to-poor fit-up conditions, were required to complete one cab assembly. Average weld length was 4 in.

Attempts had been made to join this assembly manually by shielded metal-arc welding. However, too much melt-through occurred and the welds required cleaning to prepare the surface for a paint finish. Gas welding was found to be fast, for the positions involved, and to produce smooth welds, even where mismatch was encountered. Little finishing was required.

Table 3 gives the operating conditions. Two sizes of welding rod were used, depending on the amount of sheet separation that had occurred during fit-up. Distortion and melt-through were not encountered.

Welding of Pipe

In pipe welding, the weld is usually made from the outside. Care and skill are required to deposit a weld that will

(a) Based on pipe ends beveled to 45° ± 2½° (90° included angle), and welded in the horizontal-rolled position. For welds made in the horizontal-fixed or the vertical position, welding time should be increased approximately 15%. Nominal pipe size and wall thickness are specified in ANSI B36.10-1959. Data are for average production reported by one manufacturer.

penetrate to the inner surface of the pipe without causing objectionable drop-through. Preparation of weld grooves that are large enough to permit manipulation of the torch and to facilitate adequate penetration is discussed in the section on Joint Design and Edge Preparation in this article.

After beveling, the pipe is aligned and tack welded in three or four places to maintain alignment during welding. The pipe ends are usually separated by 1/16 to ⅛ in. to provide a root opening.

Tack welds, whether used to join pipe ends or to support the adjacent edges of a seam to be welded, should be small and have a general appearance as shown in Fig. 14. Such a tack weld will make it possible to blend the tack with the main weld as it is deposited, and thereby to produce a smooth finished weld. Also, a tack weld with a smooth contour makes it easy to obtain fusion where the main weld must be connected with the tack weld.

Welding positions for pipe are determined by the conditions under which the weld can be made. The three basic positions are horizontal rolled, horizontal fixed, and vertical (Fig. 15).

In the horizontal-rolled position (Fig. 15a), the axis of the pipe is essentially horizontal and the pipe is rotated about its axis. For circumferential butt joints, welding is usually done within an angle of about 20° to 45° from the top center of the pipe.

In one frequently used procedure, the pipe is held stationary and the torch is moved to weld a segment. The pipe is rotated to a new position after each segment of the weld has been completed.

A simple fixture for rolling pipe in the field is shown in Fig. 15(b). Depressing the treadle rotates the pipe through a small arc. Then, with the pipe held stationary, the action of the weight causes the treadle to return to its up position. The cycle is repeated a sufficient number of times to rotate the pipe through the desired arc. Other devices can be used to roll the pipe; the simplest approach is to roll the pipe manually on a table or other flat surface, holding it stationary for welding.

The most efficient method of rolling pipe in a plant is by means of power-driven turning rolls. Pipe can also be set on rollers and hand cranked by means of a chain tong.

In the horizontal-fixed position (Fig. 15c), the axis of the pipe is essentially horizontal and the pipe is not rotated. Whether the pipe is supported from below or from above (as shown in Fig. 15c), the supporting members must allow access for welding. For circumferential butt joints, welding can start at the center of either the top or the bottom, and then proceed to the opposite point. The procedure is repeated for the other side of the pipe. Welding actually proceeds from flat to vertical to overhead, or vice versa, depending on whether the start is made at the top or bottom of the joint.

In the vertical position (Fig. 15d), the axis of the pipe is essentially vertical and the pipe may or may not be rotated. With the pipe vertical, a circumferential butt weld is in a horizontal position regardless of whether the pipe is rotated or not.

Rod and Torch Movements. The backhand technique for butt welding pipe in the horizontal-rolled position is illustrated in Fig. 16, with views showing the positions and movements of the welding rod and flame. When the pipe is horizontal and fixed, part of the welding must be done in the vertical position. Figure 17 illustrates how the movement of the end of the welding rod is changed to spread out and widen the weld puddle, although the puddle itself is kept small and shallow in order to control the molten metal.

For butt welding pipe in the vertical position, the positions and movements of the welding rod and flame in the backhand technique shown in Fig. 18 assist in controlling the weld puddle.

Applications. Although gas welding can be used to join pipe of any size and of many different materials, the process is most useful for welding small-diameter carbon steel pipe. Joining carbon steel pipe in diameters up to about 4 in. and in wall thicknesses up to ⅜ in. by gas welding has often proved more economical than by arc welding.

Gas welding offers control over the viscosity of the weld puddle, which is advantageous when pipe is welded in difficult positions. An incidental benefit derives from the fact that gas welding equipment can be easily converted to gas cutting equipment, and a pipe welder who is also an experienced pipe fitter should be capable of cutting almost any type of transition joint that may be required.

Standard-weight (schedule-40) carbon steel pipe up to about 10 in. in diameter can also be gas welded. Although these larger diameters are more efficiently welded by other methods, it is often expedient to use gas welding rather than to change to another process during a piping installation (see Example 511). Data for single-pass gas welding of standard and schedule-40 low-carbon steel pipe, in sizes from ½ to 10 in. and for wall thicknesses from 0.109 to 0.365 in., are given in Table 4.

In the pipe industry as a whole, arc welding plays the dominant role. In some applications, special arc welding techniques have been developed to obtain high joint integrity and greater freedom from human error. However, gas welding applications include pipe systems used in buildings and in various industrial installations for steam and hot-water heating, cooling and air conditioning, gas and air distribution, water distribution, certain types of electrical transmission, and transmis-

Table 5. Conditions Employed for Gas Welding 3-In., 6-In. and 8-In., Schedule-40 Low-Carbon Steel Pipe (ASTM A53) (Examples 509, 510 and 511)

Condition(a)	Example 509	Example 510	Example 511

(a) In all of the examples, a circumferential butt joint was welded, weld groove was a 45° V, the horizontal-fixed position was used, and welding was done in a single pass.

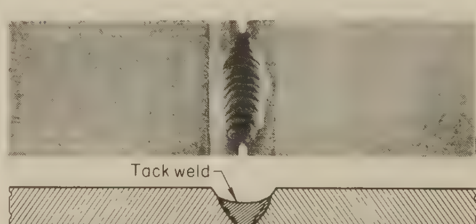

Fig. 14. Preferred contour and relative size of tack weld to obtain successful fusion with main butt weld in pipe

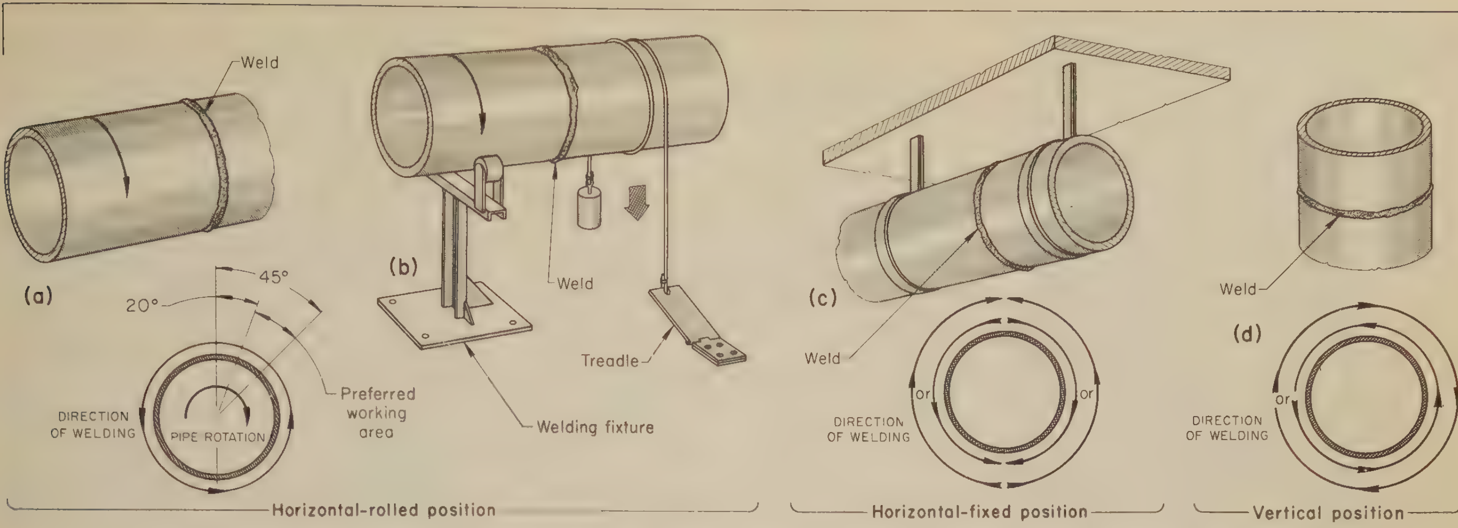

Fig. 15. Three basic positions for welding pipe and a simple turning fixture for welding in the horizontal-rolled position

sion of various commercial fluids. In fact, the welding of small-diameter low-pressure steel pipe is probably the major application of gas welding.

The three examples that follow illustrate welding procedures used for making typical circumferential butt welds in three sizes of low-carbon steel pipe.

Examples 509, 510 and 511. Gas Welding 3-In., 6-In. and 8-In. Schedule-40 Low-Carbon Steel Pipe

Example 509 — 3-In. Pipe (Table 5). The elbow joint shown in Table 5 was typical for a 3-in. local gas-distribution line installed by a piping contractor. It was gas welded using the operating conditions given in Table 5. The welding crew, typical of crews for this work, consisted of experienced gas welders certified for welding pressure pipe. Pipe was cut to size and machine beveled at the site, as required. After alignment and tack welding, the pipe was single-pass gas welded in the horizontal-fixed position. Although operating pressure in the pipeline was 20 psi maximum, the welded joints were tested at approximately 100 psi, with soap and water. No weld defects were found.

Example 510 — 6-In. Pipe (Table 5). A schedule-40 pipeline was welded by a contractor under the conditions shown in Table 5. Where beveling was required, the pipe was machined to a 22½° bevel, which provided a V-groove of 45°. Joints were gas welded in a single pass. Working pressure of the 6-in. pipe was 100 psi, but joints were tested hydrostatically at 400 psi.

Example 511 — 8-In. Pipe (Table 5). A gas company regularly employed a gas welding crew for the installation of small-diameter gas transmission lines. These pipelines sometimes included pipe of larger diameter that was also gas welded, because to change crews and process equipment was not practical. Table 5 shows the joint and gives operating conditions used for welding 8-in.-diam pipe. As with the smaller pipe, the butt joint was welded in a single pass. The V-groove was smaller than that commonly used (see the discussion headed "Pipe" on page 572), but the weld was satisfactory under a hydrostatic-test pressure of 500 psi.

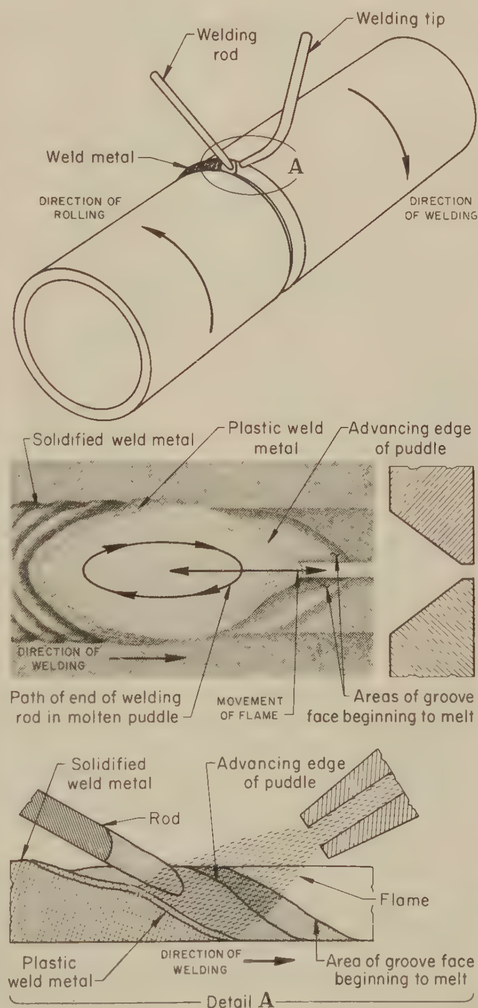

Fig. 16. Positions and movements of welding rod and flame in backhand technique used to butt weld pipe in the horizontal-rolled position

Welding of Thin-Wall Tube

In many respects, the welding of thin-wall tube (⅛-in. wall or less) is similar to the welding of sheet of the same thickness; in other respects, it is similar to the welding of pipe. Gas welding is often preferred for welding thin-wall tube, especially in small diameters, because the equipment is relatively easy to manipulate in confined spaces. Also, there is less risk of overheating and melting through the tube wall. Weld spatter is negligible.

The following examples describe the conditions that determined the selection of gas welding for joining thin-wall, low-carbon steel tube.

Example 512. Gas Welding an Exhaust Assembly for a Truck Engine (Table 6)

Two pieces of 5-in. tube were joined to form an air-vent (exhaust) assembly for a truck engine. Low-carbon steel tube (welded or seamless), with a 0.050-in.-thick wall, was used for this part. A single weld on the outside of a circumferential butt

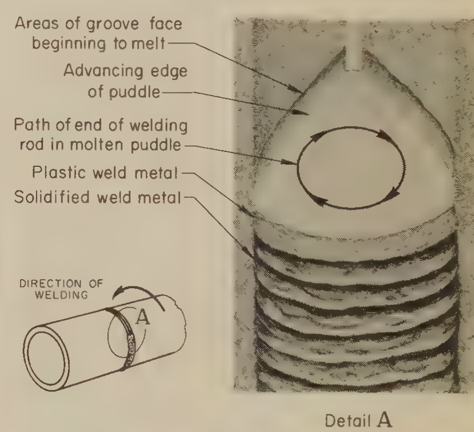

Fig. 17. Positions and movements of welding rod in backhand technique used to butt weld pipe in the horizontal-fixed position

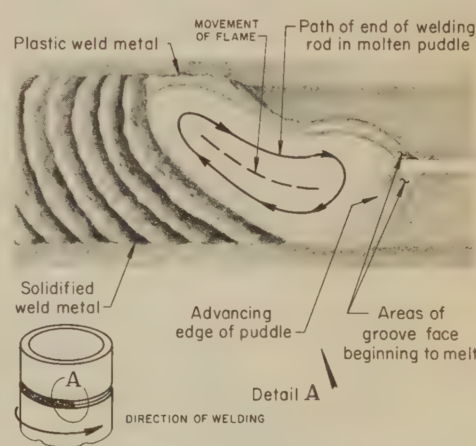

Fig. 18. Positions and movements of welding rod and flame in backhand technique used to butt weld pipe in vertical position

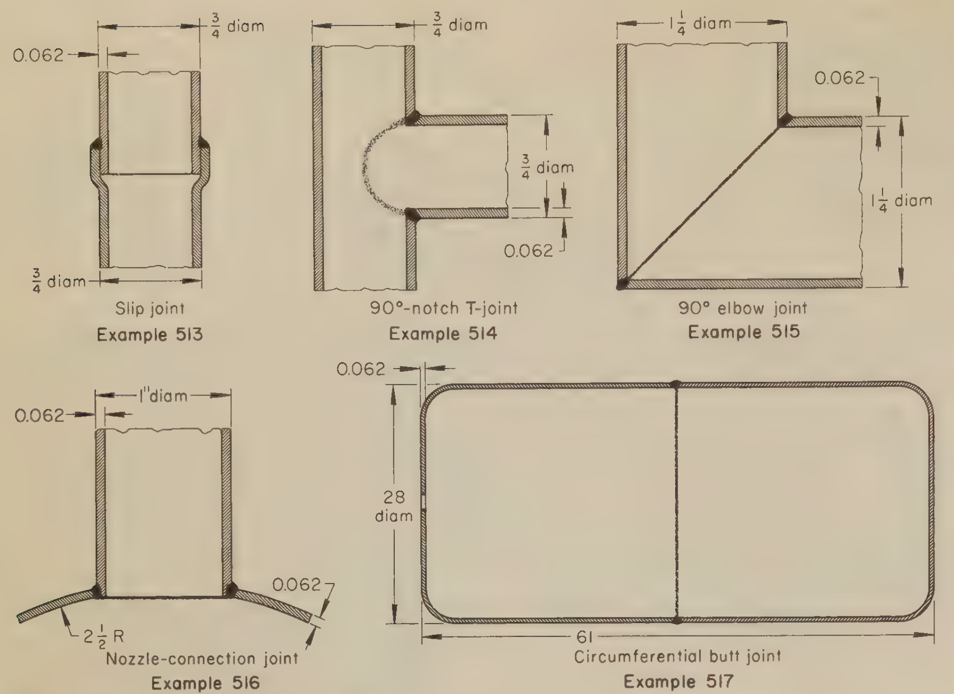

For all joints: Material was low-carbon steel tube with a 0.062-in. wall; welding rod was RG60; tip-orifice diameter was 0.0465 in.; acetylene pressure was 4 psi; oxygen pressure was 28 psi; flame adjustment was neutral; and welding was done in a single pass.
For joints shown as Examples 513, 514 and 515: Pressure employed in hydrostatic testing was 450 psi.

Fig. 19. Typical refrigerator-tubing joints that were gas welded (Examples 513 to 517)

joint was used to join a straight section of tube to an elbow.

In gas welding this assembly, no special joint preparation or welding fixture was used. The two parts were fitted and they were tack welded at four places while resting on a flat steel welding table. One side was welded, the assembly was rolled over, and the other side was welded. Welding conditions are given in Table 6.

Regulator settings for gas pressures were unusually high, especially for oxygen. Because the gas pressures were throttled down by the torch inlet valves to usable proportions, exact torch pressures were not known. However, the equal-flow requirements of the neutral flame, as well as tip size and metal thickness, indicated that actual torch pressures were not far from normal. It was claimed that higher welding speeds were obtained in this manner. Distortion, melting through or service failures have not been encountered with the joint.

Welding conditions were basically the same for the five different joints described in the next five examples. Welded low-carbon steel tube having a 0.062-in.-thick wall was used to convey

Table 6. Conditions Employed for Gas Welding an Exhaust Assembly (Example 512)

Base metal	Low-carbon steel
Wall thickness	0.050 in.
Welding rod	1/16 in., RG60
Torch type	Semi-injector
Tip-orifice diameter	0.0394 in.
Acetylene pressure	12 psi
Oxygen pressure	50 psi(a)
Flame adjustment	Neutral
Joint	Butt
Welding position	Horizontal rolled(b)
Number of passes	One
Weld length	15.7 in.
Welding time	1 min

(a) Regulator setting only (see text). (b) Welded on one side on a table, then turned over and welded on the other side.

liquid refrigerant in gas-operated refrigerators of both home and commercial types. Some of the tubing operated at 250-psi maximum pressure; this tubing was hydrostatically tested at 450 psi. Braze welding was ruled out for these applications because of the risk of galvanic corrosion between copper alloy filler metal and steel tubing. Arc welding was not used because of difficulty in controlling heat input to avoid melt-through. Gas welding avoided these difficulties and also proved more flexible in obtaining access to joints in confined areas.

Examples 513 to 517. Gas Welding Refrigerator Tube

Example 513 — Slip joints (Fig. 19) were made by expanding one end of a piece of tube to receive the mating part and then depositing a single fillet weld around the open joint. This joint was usually made on a moving conveyor line with the tube in the vertical position. Welding conditions are given with Fig. 19.

Example 514 — T-joints (Fig. 19) were cut to size, aligned, tack welded, and welded on a bench as subassemblies. Full-penetration welds were produced. The welding sequence was to complete one side, roll the work over, and then weld the opposite side. The joint detail is shown in Fig. 19, and welding conditions are given in the table with Fig. 19.

Example 515 — Square (90°) elbow joints (Fig. 19) were used to join tube for subassemblies. Welding was done on a moving conveyor line, where it was not always possible to position the joint favorably. Complete-penetration welds were made in 1¼-in.-diam tube in approximately the position shown in Fig. 19. Welding conditions are given with Fig. 19.

Example 516 — Nozzle-connection joints (Fig. 19) were made by welding various diameters of tube to a formed disk of low-carbon steel of the same thickness as the tube. Parts were assembled and welded on a bench. The disk rested on the bench and the tube was positioned on the disk. A single fillet weld was made from the outside.

Example 517 — Circumferential butt joints (Fig. 19) on small storage tanks of 0.062-in.-thick low-carbon steel were gas welded using small turning rolls to rotate the work. A single, full-penetration butt weld was deposited from the outside. Tube connections were located and welded in place in a later operation. Welding conditions are given with Fig. 19. The joint was tested later for tightness at a low static head. The tanks were processed together with the tubing. The type and thickness of material and welding procedure were the same as in the four preceding examples.

Repairs and Alterations

Gas welding is frequently used for repairs and alterations because the equipment is portable, welding can be done in all positions, and acetylene and oxygen are readily available. Also, gas cutting, braze welding, brazing or flame heating are often needed and

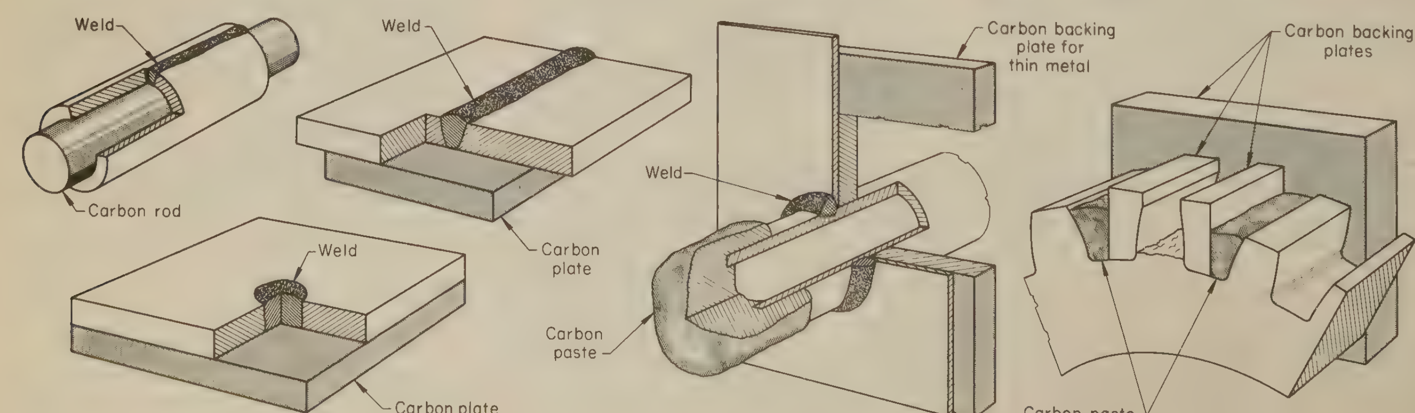

Fig. 20. Carbon backing and support to expedite repair welding of surfaces and contours

the same personnel, equipment, and gases required for these operations can be used for gas welding.

On many repair welding jobs, sections that must be rebuilt to specific contours or dimensions require backing to support the weld metal. Carbon paste, which can be molded, or carbon plate, which can be easily machined, can be used for backing, as shown in Fig. 20. To avoid carbon pickup, copper or a thick steel plate can be used, if care is taken to prevent welding of the backing to the part.

Edge preparation for repair work and alterations is described on page 572 in this article. To ensure complete crack removal, liquid-penetrant or magnetic-particle testing can be used. Parts under stress must not be cut or welded. Repairing a tank can be dangerous (see AWS A6.0-65, Safe Practices for Welding and Cutting Containers That Have Held Combustibles).

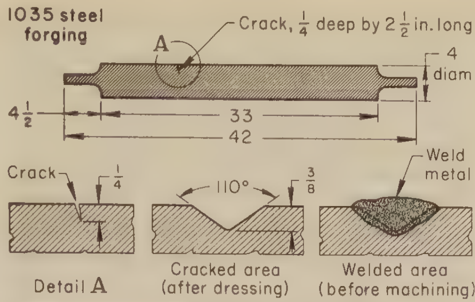
In many applications of repair welding, elaborate precautions are not needed. The following example describes the repair of a cracked steel roll.

Example 518. Use of Gas Welding for Repairing a Cracked Roll (Fig. 21)

A crack approximately ¼ in. deep and 2½ in. long developed in a roll 4 in. in diameter by 42 in. long. The roll (Fig. 21) was a 1035 steel forging.

To avoid purchasing a new forging and undergoing the expense of machining the roll surface, splines and keyways, the crack was repaired by welding. Gas welding was selected because it produced a lower temperature gradient at the weld than arc welding and because the gas torch provided a convenient source of heat for local preheating and for postweld heat treating.

First, the crack was dressed out by gas gouging to sound metal, to provide a V-groove with an included angle of about 110°. The area around the groove was preheated to 400 F and then weld metal was deposited. After welding, the joint area was wrapped in asbestos and allowed to cool to room temperature. Before the weld was machined, it and the heat-affected zone were partly stress relieved for ½ hr at 1050 F, by use of a gas torch. Temperature-indicating crayons were used to establish preheat and stress-relief temperatures. Operating conditions are summarized in the table accompanying Fig. 21.



Welding rod	3⁄32 in., RG65
Torch	Injector type
Tip-orifice diameter	0.0980 in.
Acetylene pressure	5 psi
Oxygen pressure	30 psi
Flame adjustment	Neutral
Welding position	Flat
Preheat and interpass temperature	400 F
Stress relief (partial)	1050 F, ½ hr

Fig. 21. Roll in which a small crack was repaired by gas welding (Example 518)

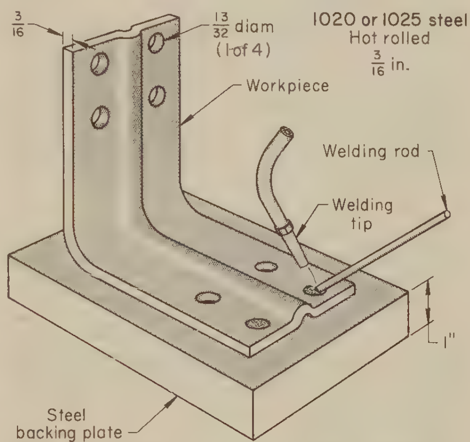
When gas welding is used to correct production parts that would be rejected because of a small error or defect in manufacture, good judgment must be used to determine if the salvaged part, after welding, will be as good as a new part for the service. Some fabricating codes identify the defects that may be rectified by welding and define the standards for repair. Rectification may include correction of defects, building up of undersize parts, and filling in of drilled holes.

In the following example, gas welding provided a simple means of salvaging a large number of parts, without detrimental effects on serviceability.

Example 519. Salvaging Incorrectly Drilled Brackets (Fig. 22)

When a large number of brackets were incorrectly drilled, the manufacturer decided to salvage them by welding the incorrect holes and redrilling. The brackets, as shown in Fig. 22, had two 13⁄32-in.-diam holes at each end; the holes had been drilled too close to the edges. The brackets had been formed of 1020 or 1025 hot rolled, pickled and oiled steel, 3⁄16 in. thick. After forming, drilling and degreasing, the brackets had been given a coat of black primer.

To close the holes, arc welding was tried, but proved unsatisfactory. The weld metal and backing plate fused, and considerable cleanup was necessary after welding. Also, the primer had to be removed from around the holes, because it caused spatter during welding. Gas welding not only avoided these difficulties but also avoided subsequent grinding of weld surfaces. Operating conditions for gas welding are tabulated below Fig. 22.



Welding rod	⅛ in., RG45
Torch	Positive-pressure type
Tip-orifice diameter	0.0827 in.
Acetylene pressure	7.5 psi
Oxygen pressure	15 psi
Flame adjustment	Neutral, to slightly reducing
Welding position	Flat
Production rate	12 to 14 pieces per hour

Fig. 22. Bracket salvaged by gas welding incorrectly drilled holes (Example 519)

Altering equipment to make it suitable for new uses is another application for gas welding.

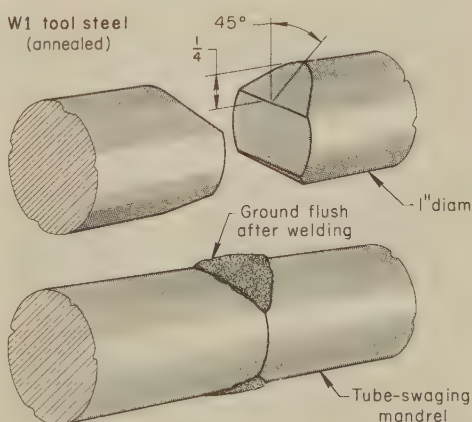
Example 520. Altering Tube-Swaging Mandrels (Fig. 23)

Tube-swaging mandrels were lengthened by welding extension pieces to them. The mandrels were made of annealed W1 water-hardening tool steel (0.85% C), and ranged in diameter from ½ to 2 in. Attempts to join the extensions to the mandrels by arc welding were unsuccessful. Partial-penetration gas welds, as shown for a 1-in.-diam mandrel in Fig. 23, provided adequate strength during swaging, and simplified separation when the extra length was no longer required. Gas welding was successful because it provided better control over the heating and cooling cycle.

Welding procedure was as follows:

1 Bevel both sides of each bar 45° (see Fig. 23), fit, and tack weld.
2 Preheat to 600 F for a distance of 4 in. on both sides of the joint. Use temperature-indicating crayons.
3 Weld both sides of joint, maintaining temperature, as above.
4 Immediately after welding, wrap joint in asbestos rope and allow to cool to room temperature.
5 Remove insulation and heat to 1050 F; hold at temperature for ½ hr. Use gas torch and temperature-indicating crayons.
6 Cool in air.

Operating conditions used for welding 1-in.-diam mandrels are given in Fig. 23.



Welding rod	3⁄32 in., RG60
Torch	Injector type
Tip-orifice diameter	0.0760 in.
Acetylene pressure	9 psi
Oxygen pressure	40 psi
Flame adjustment	Neutral

Preheating and Postheating

Preweld and postweld heat treatments are not usually required to reduce the hardness of low-carbon steel, but either or both treatments are beneficial and can be effective in avoiding or reducing distortion. Most steels that are gas welded fall within the low-carbon range.

Gas welding distributes a large amount of heat over a wide area. This results in relatively slow cooling rates and relatively low stress gradients, which, in turn, reduce the degree of hardening and the magnitude of residual stresses that are usually associated with welding heat cycles.

In Examples 518 and 520 in this article, preweld and postweld heat treatments were applied by using the heat of the gas flame. In the example that follows, gas welding eliminated cracking in a steel that had a carbon equivalent of 0.55 to 0.65% and could therefore be considered borderline as to the need for heat treatment.

Example 521. Use of Gas Welding To Eliminate Postweld Tempering (Fig. 24)

Aircraft landing-gear side-stay assemblies, shown schematically in Fig. 24, consisted of three end fittings of 1330 steel (0.28 to 0.33% C, 1.60 to 1.90% Mn) joined in the form of a trapezoid by three 1330 steel tubes measuring 2½ in. in outside diameter by ⅛ in. in wall thickness. The as-

Oxygen pressure	28 psi
Flame adjustment	Neutral

Fig. 24. Aircraft landing-gear support that was gas welded to eliminate need for postweld tempering (Example 521)

sembly was originally welded by the shielded metal-arc process; E7016 electrodes were used. Several assemblies cracked in a tube adjacent to a weld after a short time in service. Examination revealed that, in the heat-affected zone, hardness was as high as Rockwell C 50. The high hardness was caused by the chilling effect of the large mass of metal in the end fittings. A postweld tempering treatment at 1200 F to reduce the high hardness could not be used, because the tubes became distorted.

Local stress relief of the welded joints with a gas torch was then tried. This method was successful but laborious, and it was finally decided to gas weld the assembly. Hardness tests in the area of the welded joint showed that the maximum hardness in the heat-affected zone was 285 Brinell (Rockwell C 29). This was only moderately higher than the hardness of the end fittings and tubes, which had a hardness of 223 Brinell (Rockwell B 98). The improvement was believed to result from the wider area heated during gas welding, which produced a lower temperature gradient. Operating conditions for gas welding are given with Fig. 24.

Bridging Gaps in Poor Fit-Ups

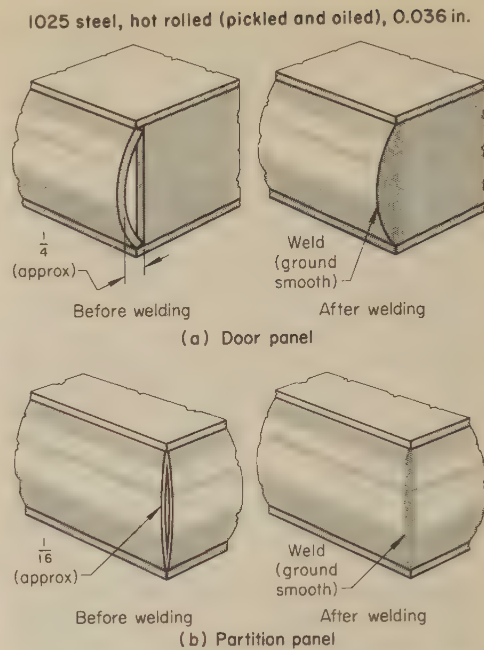
The ability to control the flow of molten weld metal in gas welding provides a high degree of versatility in bridging large gaps caused by a poor fit-up. By manipulation of the gas torch, weld-metal temperature can be held to the minimum, and the pressure of the gas flame can be used to help support the weld puddle in any position, including overhead.

The two examples that follow describe how gas welding was used to bridge gaps in fit-up. In the first example, gas welding was standard procedure; in the second, it was optional.

Example 522. Use of Gas Welding To Produce Neat Welds Where Fit-Up Was Poor (Fig. 25)

Partitions and partition doors, such as those used for office cubicles or lavatory stalls, were produced as panels consisting of two sheets of 1025 steel separated approximately 1 in. by formed strips that were fitted around the sides. Figure 25 shows a door panel and a partition panel before and after welding. The door panel, Fig. 25(a), had rounded strips down the sides and flat strips at the top and bottom. Where the rounded and flat strips intersected at the corners, a gap was formed in the shape of a circular segment with a ¼-in. rise. The partition panel, shown in Fig. 25(b), had rounded strips on all sides. These strips intersected in a mitered joint having a gap that was usually not more than 1/16 in. wide. The gaps in both types of panels were filled by gas welding as the strips were joined to the sheet. This method was easy to use and it produced smooth welds that required little grinding or finishing.

The gaps with the ¼-in. opening required 12 sec to weld. A small spacer was used to help fill the gap. The mitered joints required 9 sec to weld. Two men usually worked together on each panel. Other welding conditions were the same for both panels (see table with Fig. 25).



Welding Conditions
(For both panels, except where noted)

Welding rod	1/16 in., RG60
Tip-orifice diameter	0.0465 in.
Acetylene pressure	5 psi
Oxygen pressure	17 psi
Flame adjustment	Neutral, to slightly reducing
Number of passes	One

Welding time, partition panel	9 sec
Grinding time, door panel	15 sec

Fig. 25. Panels that were gas welded to obtain a neat joint despite gaps of varying size (Example 522)

Example 523. Gas Welding of Corner Joints in Tread Plate (Table 7)

Steps for the cab-door entrance of trucks were formed from single sheets of 16-gage (0.060 in.) four-way tread plate of hot rolled, low-carbon steel. The steps had flanges 1½ in. deep on all four sides. A closure weld was required at each of the four corners. Both arc welding and gas welding were used. When the corners were tightly formed, either process produced satisfactory joints, but because of the nonuniform cross section of the tread plate, accurate bending was difficult and large gaps often occurred at the corners. Under these conditions, gas welding was preferred. Gaps were filled and seams were welded in a single pass.

The welding conditions listed in Table 7 show gas pressures that are higher than those normally recommended for the tip-orifice diameter used. The pressures were reduced by adjustments of the inlet valves on the torch to give the desired flame characteristics. It was believed that higher welding speeds could be obtained by this means than by adjusting the gas regulators to the recommended gas pressures.

Example 508, page 573, describes another application where gas welding bridged gaps when fit-up was poor.

Table 7. Conditions for Gas Welding Corner Joints in Tread Plate (Example 523)

Base metal	Low-carbon steel
Thickness of base metal	0.060 in.
Welding rod	3/16 in., RG60
Torch	Equal pressure
Tip-orifice diameter	0.0675 in.
Acetylene pressure	12 psi

Flame adjustment	Neutral
Welding position	Flat
Welding time per joint	30 sec

(a) High regulator setting was preferred by welder for fast production; however, flame was adjusted to neutral at the torch.

Safety

The gases employed in gas welding may form explosive mixtures if incorrectly handled, and burning of these gases must be controlled within recommended limits for safety of the welder and surrounding property.

The incorrect operation of gas welding equipment by untrained personnel can cause serious accidents. Therefore, before gas welding equipment is installed or operated, the safety rules regarding its use should be thoroughly learned.

Federal, state and local governments have adopted many safety rules that are legally enforceable. In addition, equipment manufacturers, gas suppliers, and regulatory agencies have cooperated in the publication of documents regarding safety in gas welding, with which the user should be familiar. The major sources of safety rules and recommendations are:

Oxyacetylene Pressure Welding

OXYACETYLENE pressure welding is a process in which heat from oxyacetylene flames is used in conjunction with pressure to produce a solid-phase weld. Common applications include joining pipe sections, aircraft landing-gear components, railroad rails, and drill bits (to shanks). Most higher-melting alloys, including carbon and low-alloy steels, stainless steels, and heat-resisting alloys, can be successfully oxyacetylene pressure welded. The process has not proved successful for welding aluminum and magnesium alloys.

Principles of Operation. Although there is more than one method of oxyacetylene pressure welding, this article deals only with the closed-gap method.

Closed-gap welding is accomplished by either of two techniques. In one, called single-pressure welding, first the workpieces are butted together under a pre-established imposed pressure, and then the joint is surrounded with oxyacetylene torches to heat it until a given amount of upsetting has taken place. In the other technique, called double-pressure welding, the workpieces are butted together under an initial pressure, the joint is heated to a given temperature, and then the pressure is increased to accomplish the upsetting. Workpieces being heated for closed-gap oxyacetylene pressure welding are shown schematically in Fig. 1.

Advantages. Oxyacetylene pressure welding is faster than welding that entails fusion, and does not develop a cast structure in the weld zone. No inclusions or porosity are introduced during welding, and no molten metal is squeezed out as flash (as in flash welding). The metal in the weld zone is capable of the same response to heat treatment as the base metal. Susceptibility to cracking is minimized, because the temperature gradients developed during welding are not steep.

Limitations. Oxyacetylene pressure welding is slow compared with other pressure welding processes. Butting surfaces of the workpieces must be flat, parallel and clean, thereby increasing the cost of surface preparation.

Bars up to 3-in. diam and tubes as large as 25-in. OD have been welded by the closed-gap method. However, in welding thick-wall tubing or large-diameter bars, time is required for transmitting enough heat inward to metal farthest from the surface. This difficulty can be alleviated by the use of a tapered joint design.

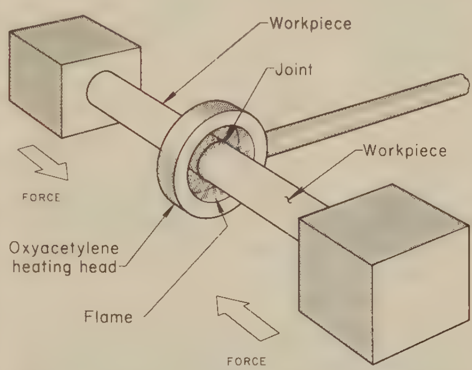

Fig. 1. Setup for heating workpieces for closed-gap oxyacetylene pressure welding

Table 1. Typical Conditions for Oxyacetylene Pressure Welding of Carbon Steel Pipes (a)

Wall thickness, in.	Welding time, sec	Total shortening, in.	Pipe-end bevel
0.187	45	0.25	4°
0.203	50	0.265	4°
0.238	55	0.300	4°
0.250	60	0.312	5°
0.375	90	0.412	6°

(a) Using the double-pressure method, with initial pressure 1000 psi of pipe cross section and final pressure 4000 psi of pipe cross section.

Joint Design. The butt ends of thicker sections (tube walls thicker than ¼ in. or solids thicker than ½ in.) are usually tapered. Tapering serves two purposes: (*a*) it facilitates heat penetration, and (*b*) it helps to control the shape of the upset. Carbon steels are generally beveled to a 6° to 10° included angle, with the open side, or gap, being exposed to the flames. This gap is closed during upset. For alloy steels, a much flatter included angle (140° to 150°) is used on outside diameters, and an included angle of 140° to 170° is used on inside diameters when tubing is being welded.

Typical Procedure. A typical sequence of operations for oxyacetylene pressure welding of hollow, 4135 steel landing-gear components by the closed-gap method is as follows:

1. The butting surfaces of parts are tapered on the outside and inside diameters to control upset contour, and are machined to a finish of 100 micro-in. or smoother.
2. Parts are loaded into the welding machine, and accuracy of alignment is checked by inserting a sheet of vellum between butting surfaces and pressing them together. When pressure is released, the vellum is examined for uniformity of contact around the entire circumference. Adjustments are made until uniformity is achieved.
3. The weld faces are cleaned with solvent and lint-free cloths, and a pressure of 4000 psi is applied to the weld area.
4. The heating head is brought into position and lighted, and the oscillating mechanism is started. The heating head is oscillated longitudinally (and sometimes radially, as well) to prevent localized overheating.
5. When the predetermined amount of upset has taken place, thrust and heat are discontinued and the part is allowed to cool to a black heat in the machine.

Typical conditions for oxyacetylene pressure welding pipes of various wall thicknesses are presented in Table 1.

Oxyacetylene Braze Welding of Steel and Cast Irons

OXYACETYLENE braze welding is a method of gas welding capable of joining many base metals but used primarily on steel and cast iron with a copper alloy filler metal (rod) and a flux. Braze welding is similar to torch brazing with a filler rod, except that joint openings are wider and distribution of filler metal takes place by deposition rather than by capillary flow. Equipment and some filler metals used in braze welding are the same as those used in torch brazing (see article that begins on page 619).

In braze welding of ferrous metals, the base metal is not melted. The filler-to-base-metal bond is the same as in torch brazing. Flux is applied to the joint surfaces, which, together with the surrounding area, are preheated to the point where the filler metal will wet or "tin" these surfaces. During welding, tinning precedes the weld puddle.

Applicability

Braze welding is used for making groove, fillet, plug or slot welds in metal ranging from thin sheet to heavy castings. Weld layers can be built up, as in gas welding.

The process is often used as a low-temperature substitute for gas welding or a low-cost substitute for brazing. Braze welding resembles brazing in two respects: (*a*) nonferrous filler metals are used, and (*b*) bonding is achieved without melting the base metal. On the other hand, braze welding resembles welding because it can be used for filling grooves and for building up fillets as may be required.

Major advantages of braze welding include: (*a*) joints are made at lower temperature than in gas or arc welding, thus minimizing thermal stress and distortion, as well as susceptibility to cracking; (*b*) the weld deposit is relatively soft and ductile, providing machinability and low residual stress; (*c*) joints with good strength and generous fillets can be produced (fillets often add strength for specific types of loading in service); and (*d*) the equipment is simple and well-suited to on-site repair applications.

Disadvantages of braze welding are: (*a*) weld and base-metal colors do not match; (*b*) weld strength, while usually adequate, is limited by the strength of the copper alloy used, and thus to service below 500 F; (*c*) joints are subject to galvanic corrosion and to differential chemical attack.

Braze welding is very often used in production joining applications; three are described in Examples 524, 525 and 526 in this article. The process is

Table 1. Compositions of Filler Metals Used for Braze Welding (AWS A5.7-69)

also used extensively for repairing broken or defective steel and cast iron parts (see Example 527). Braze welding is sometimes used for repairing cast iron castings in the foundry, although the color mismatch imposes a restriction on its use for this purpose.

Another frequent application of braze welding is in machine shops, for correcting machining errors or modifying in-process parts.

Shop maintenance departments and toolrooms use braze welding for repairing tools and pieces of equipment ranging from small hand tools to large cast iron press frames.

Mobile repair units such as those that accompany grain-harvesting crews usually carry equipment for braze welding so that harvesting machinery can be quickly repaired in the field when damaged.

Flame Adjustment

For carbon steels, the oxyacetylene flame for braze welding is adjusted to the neutral condition. For cast irons, the flame is adjusted to a slightly oxidizing condition by increasing oxygen or decreasing acetylene flow, which reduces the telltale acetylene "feather". When the feather disappears and the inner cone becomes slightly necked, the flame is oxidizing. This type of flame removes the graphite from surfaces of cast iron.

Air is not used as the combustion agent in braze welding, because it results in slow heating.

Filler Metals

The four copper-zinc or copper-zinc-nickel filler metals for which compositions are given in Table 1 are those most often used for braze welding. These four compositions are available as welding rods in the standard diameters from 1/16 to 1/4 in.; length is usually 36 in. The order in which the four filler metals are listed in Table 1 is roughly that of increasing tensile strength. All-weld-metal tensile strengths of the compositions shown range from approximately 50,000 to 70,000 psi. Melting temperatures of these alloys range from about 1600 to 1800 F.

RBCuZn-A (naval brass) rods contain up to 1% tin, which improves strength and corrosion resistance. These filler-metal rods are especially suited for use with oxyacetylene, and are considered as general-purpose rods for braze welding of steel and the various grades of graphitic cast iron.

RCuZn-B (low-fuming bronze) rods are similar to RBCuZn-A, but contain additions of iron, manganese, silicon and nickel, which serve to increase strength, and to reduce vaporization of the zinc (hence the name "low-

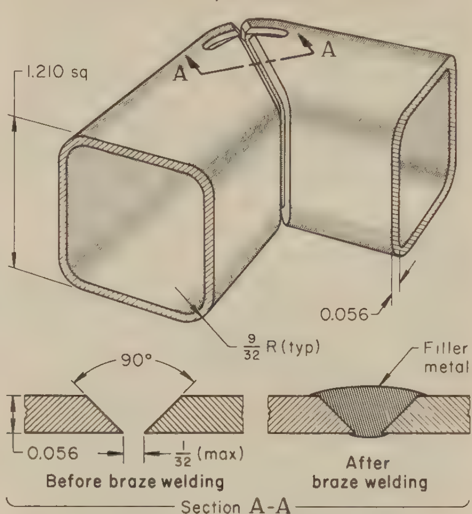

Fig. 1. Mitered corner joint in a tubular part used in manufacturing metal furniture. Poor appearance of plated joint was eliminated by a change in filler metal used in braze welding. (Example 524)

fuming"). RCuZn-B rods may be used for joining either steel or cast iron, and sometimes these rods are also used for surfacing steel or cast iron for wear resistance.

RCuZn-C rods are also low-fuming bronze rods, and are of the same composition as RCuZn-B except they do not contain nickel. RCuZn-C rods provide as-welded mechanical properties that are higher than those obtained with RBCuZn-A, and are widely used as general-purpose rods for braze welding of both steel and cast iron.

RBCuZn-D (nickel silver) rods have lower copper and higher nickel contents than those of the three other filler metals listed in Table 1. Because of this difference in composition, the deposit from an RBCuZn-D rod is whiter and is thus used for braze welding when closer color match is important. RBCuZn-D provides the highest as-welded strength of the four braze welding filler-metal alloys that are discussed here.

Joint Properties. Joints braze welded with one of the RCuZn filler metals have tensile strength at room temperature that usually ranges from 40,000 to 60,000 psi, depending on the filler metal used. The strength of the joint drops off very quickly at temperatures above 500 F. Color match with the base metal is not usually obtained, but where color is important the RBCuZn-D (nickel silver) rod is used. The bimetallic joint is subject to galvanic corrosion and is less resistant to alkaline solutions than the ferrous base metal.

The following example illustrates the use of braze welding in a conventional production operation on thin low-carbon steel, where difficulties were overcome by a change in filler metal.

Example 524. Change in Filler Metal That Improved the Appearance of Braze Welded Tubular Steel After Plating (Fig. 1)

Metal furniture parts made of low-carbon tubular steel conventionally were braze welded at corner joints. High rejection rates (25%) because of poor appearance were encountered when mitered joints of the type shown in Fig. 1 were nickel-chromium plated after braze welding. An investigation of the entire fabricating procedure showed that nearly all of the rejections could be eliminated by a change in filler metal. Details of the original procedure, the causes of rejections, and the revised procedure are discussed in the paragraphs that follow.

Preparation for braze welding was the same for both procedures. Tubing joints were sawed at a 45° angle, clipped at the corners for bending, and press formed at the outer side, as shown in Fig. 1. The joint edges were then beveled at 45° on all four sides. Without cleaning, the parts were assembled in a fixture to give a 1/32-in. maximum clearance at the joint. An oxyacetylene torch with an 0.0595-in.-diam tip was used with both procedures. In both cases, flux was added by gas fluxing through the flame. [Gas fluxing is described on page 629, in the article on Torch Brazing of Steel.]

In the original procedure, a rod of copper-zinc alloy RCuZn-C was used as filler metal, the joint being braze welded on all four sides. Before being plated, the weld was ground flush, buffed and chemically cleaned. Cleaning time varied because the manual braze welding operations were not uniform as to heating time, and the amount of smut left on the parts varied accordingly. The following difficulties occurred during cleaning and plating.

1. Conventional alkaline and acid solutions used in the cleaning process attacked the filler metal, causing voids and, in some assemblies, roughness, all of which were apparent after plating.
2. Time of exposure during cleaning was critical. Overexposure caused severe etching. Cleaning time was difficult to control because of lack of uniformity in heating during brazing.
3. Because of the softness of the filler metal, feather edges were left on the surface at the bond lines after grinding and buffing. The feathers were etched off during cleaning, but a sharp ridge was left that became an area of apparent nickel buildup during plating.
4. Color difference between filler and base metal was apparent after plating, outlining the joint.

By changing the filler metal to a rod of a different copper-zinc alloy, RBCuZn-D, the difficulties were overcome. Results of this change were:

1. The filler metal was less susceptible to attack during cleaning; voids and roughness were reduced to an acceptable level.
2. Cleaning time was less critical, giving the operator more latitude in removing smut.
3. The filler metal was harder and less likely to feather during grinding. The roughness resulting from buildup of nickel was greatly reduced.
4. Color match was improved, making the joint less noticeable.

The improvements reduced the rate of rejection after visual inspection to less than 1%. This saving more than offset the higher cost of the RBCuZn-D filler rod. In addition, higher joint strength was obtained. The change did not affect the production rate of 400 welds per 8-hr shift.

Fluxes

Fluxes for braze welding are not the same as those used for capillary brazing. Because the temperatures used in

braze welding (often higher than 1800 F) are higher than those used in most capillary brazing, and because the time of exposure to elevated temperature is longer in braze welding, the flux used must have a higher melting point and be able to withstand sustained exposure at the higher temperatures.

There are no standard specifications for braze welding fluxes. The few existing government specifications are based on composition, and the fluxes so specified are not considered as effective as the proprietary flux formulations that are available commercially. Three types of flux are in general use:

1. A basic type of flux, which simply facilitates braze welding by cleaning the base metals and aiding in the tinning operation
2. A flux, available in paste form, that performs the functions of the basic flux described above and, in addition, suppresses the formation of zinc oxide fumes from the filler metal
3. A flux, sometimes called a tinning flux, that is formulated expressly for use in braze welding of gray or ductile iron.

The first two of the above-listed fluxes are generally satisfactory for braze welding of steel and malleable iron. The second type is sometimes used with copper-zinc filler metals in capillary brazing. The third type contains iron oxide or manganese dioxide, either of which combines with the surface carbon of the gray and ductile irons; consequently, this type of flux is preferred for braze welding these cast irons.

Application of flux is done in any of four ways: (*a*) dipping the heated filler-metal rod in the flux, (*b*) brushing flux on the joint before brazing, (*c*) using flux-coated filler-metal rods, or (*d*) fluxing through the gas flame (see "Gas Fluxing" on page 629, in the article on Torch Brazing of Steel).

The use of flux-coated filler rods or gas fluxing eliminates the fluxing operation and ensures uniform application. Gas fluxing is used chiefly on steel in production (see Examples 524 and 526).

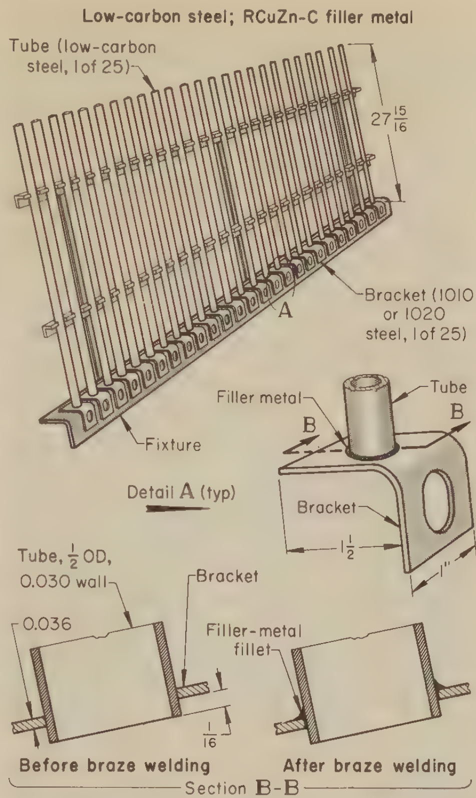
Joint Preparation

In base metals thicker than about $\frac{3}{32}$ in., the edges of butt joints for braze welding are prepared with a 90° or a 120° V-groove, to provide a wide bonding area. Fillet, plug and slot welds present naturally open faces. Edge preparation in base metals less than about $\frac{3}{32}$ in. thick can be optional; either a square groove with a root opening comparable to the thickness may be used, or a V-groove may be cut. The V-groove makes it possible for the braze welding operator to see whether the joint is properly filled; this is not always possible in torch brazing.

In applications involving thin joints with parallel-side joint surfaces and relatively close clearances, it is sometimes difficult to determine whether the joining process qualifies as brazing or braze welding, because there is some capillary action.

Cleaning Before Braze Welding

For satisfactory results in braze welding, joint edges must be as clean as possible before the operation begins. In order to obtain maximum bond strength, the joint surfaces must be bright and free of oil, rust or other foreign matter. Also, the metal surrounding the joint edges must be cleaned, both on bottom and on top.



In braze welding, production rate and joint quality were both improved in comparison with those obtained in the joining method previously used, shielded metal-arc tack welding.

Fig. 2. Tube-and-bracket assemblies that were oxyacetylene braze welded on a 25-assembly fixture, at the rate of five fixture loads per hour (Example 525)

The use of a salt bath is best for cleaning any of the cast irons prior to braze welding, just as it is for brazing (see the discussion of cleaning procedures on page 661 in the article on Brazing of Cast Irons). If a salt bath is not available, however, the procedures described in the following paragraph are reasonably satisfactory.

If the surface of cast iron has been ground, the graphitic smear can be removed by quickly heating the surface until it is dull red in color and, after cooling, going over the surface with a wire brush. If greasy or oily cast iron is ground, some of the grease or oil may penetrate the surface. If this occurs, the resulting film should be removed by painting the surface with chemically pure hydrochloric acid. After 15 minutes, the surface must be scrubbed with a wire brush and cold clean water.

Preheating and Postheating

Although it is not always necessary, iron castings may be preheated before being braze welded, to ensure success of the operation. The preheating may be local or general, depending on the size of the casting. Large castings require extensive preheating. A black preheat, or a low red heat visible in darkness (obtained at approximately 900 F), is generally used. It has been advantageous in some applications to preheat to as high as 1650 F, but temperatures above 1000 F may have an adverse effect on the wetting action of the filler metal, because of oxidation of the surfaces before braze welding.

No postheating is necessary after braze welding of cast iron. However, cooling of the braze welded assemblies is preferably retarded by wrapping them with asbestos or by the use of similarly effective methods.

Braze Welding of Steel

Braze welding of steel is faster than gas welding, because braze welding requires less heat. Overheating of the base metal must be avoided, to prevent the filler metal from failing to wet the joint surfaces. Low-carbon steels are heated no higher than 1350 F before the filler metal is deposited. Although the filler-metal alloys used in braze welding melt at temperatures between 1600 and 1800 F, the only rise in the temperature of the base metal is that incidental to deposition.

The low peak temperatures in braze welding reduce the probability of distortion and avoid the problem of melt-through in thin metals. The next example describes an application in which braze welding eliminated melt-through, increased production rate, and improved product appearance and quality for a steel tube-and-bracket assembly.

Example 525. Use of Braze Welding To Replace Arc Tack Welding (Fig. 2)

Joining 20-gage (0.036-in.) brackets of low-carbon steel to $27\frac{15}{16}$-in. lengths of ½-in.-OD by 0.030-in.-wall tubing of the same material was originally done by shielded metal-arc tack welding. Figure 2 shows a typical tube-and-bracket assembly.

The tack welding operation was generally unsatisfactory. When a single-part fixture was used, the operation was too slow. By using a multiple-part fixture, production was speeded up, but inaccurate arc strikes and melt-through resulted in many rejects and some service failures. The welder found it awkward and time-consuming to raise and lower his welding hood for each tack weld, but failure to do so caused erratic arc control.

By changing to braze welding, it was possible to use a 25-part fixture (Fig. 2) and to braze weld each part successively without interruption. A lightly flux-coated, low-fuming bronze rod (RCuZn-C) was used to deposit a fillet weld that gave a much better appearance than the tack welds and was stronger. The oxyacetylene torch was adjusted for maximum heating with a neutral flame. In playing the flame on the joints, the torch tip was generally pointed in the direction of welding progress, making a separate preheating operation unnecessary.

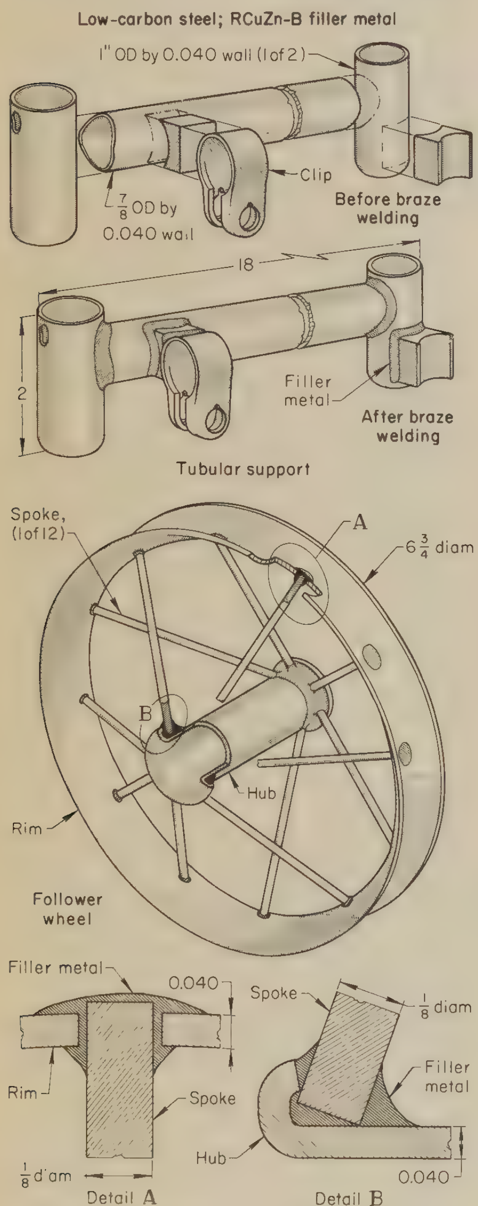
In addition to achieving a satisfactorily high production rate (125 pieces per hour, including loading and unloading), rejections were negligible. After several years in service, no tube failures were reported.

Production braze welding of metal furniture and similar products that are to be plated requires joints that are free of surface oxidation, overheated flux, and smut film. In addition to pickling, it may be necessary to grind, brush, buff and polish the joint for satisfactory plating. The cost and delay of the latter operations often can be avoided by using the procedures described in the next example.

Example 526. Copper-Zinc Braze Welding With Gas Fluxing (Fig. 3)

Braze welding with gas fluxing was the most practical method of joining the various low-carbon steel parts used in the manufacture of chromium-plated invalid wheelchairs. More than 200 joints per chair were involved in this assembly of tubing, wire, formed sheet, and formed or machined bar stock. Two typical structural subassemblies are shown in Fig. 3. The tubular support required five welds: tube-to-tube (2), tube-to-fitting (2) and fitting-to-fitting (1). The follower wheel required 12 spoke-to-rim and 12 spoke-to-hub welds. The major requirements for both subassemblies were strength, smooth appearance, platability, and speed of production.

Strength requirements were not difficult to meet, because the joints were designed so that a smoothly filleted weld deposit would provide more than adequate strength. Meeting the other requirements was a matter of skill in consistently applying optimum technique.



Torch type	Oxyacetylene
Tip-orifice size	No. 57 drill (0.043-in. diam)
Filler metal	⅛-in.-diam wire, RCuZn-B
Flux	Gas flux
Preheat and postheat	None
Assembly and brazing time	3 minutes
Production, tubular supports	120 per 8-hr shift

Fig. 3. Manually braze welded subassemblies used in the manufacture of wheelchairs. Smooth fillets and absence of overheated metal were essential. (Example 526)

Joining the parts of the tubular support shown in Fig. 3 was done at one of seven stations, each of which was supplied with oxygen and acetylene from two pipelines leading from cylinders equipped with manifolds. At each station, the tooling and fixturing used for assembling and aligning the workpieces was mounted on a pedestal adjusted to a height convenient for the operator in the standing position.

The efficiency of the procedure was based on eliminating operations that would slow production, add cost or produce questionable results. Thus, to avoid the separate application of a flux and subsequent manual flux cleaning, gas fluxing was used (see Fig. 10 and accompanying text on page 629 in the article on Torch Brazing). In addition, gas fluxing made it possible to eliminate postweld grinding, sanding and buffing prior to electroplating.

The low-carbon steel parts were processed through a solvent cleaning tank, dried, and stored at respective braze welding stations. Parts were assembled manually in a fixture and held in alignment by toggle clamps. Joint clearances for the tubular part varied from about 0.005 to 0.015 in. before heating, except for the joint at the circular clip (Fig. 3), which flared out to about ⅛ in. The oxyacetylene torch flame was adjusted to neutral with a very slight acetylene feather. Because of the brilliant green flame resulting from the presence of the flux in the fuel gas, suitably tinted goggles were worn during the adjustment.

The flame was "brushed" around each joint for a few seconds, heating the area and depositing a thin film of flux. A rod of copper-zinc filler metal, RCuZn-B, was touched to the joint at several places, heated and melted. The molten filler metal flowed through the remaining joint area and formed well-rounded fillets. Care was exercised to avoid overheating either the base metal or the filler metal. Overheated areas on the assembly, which were readily identified by burned and blackened flux and metal, could not be plated without considerable dressing. Since skilled operators could avoid overheating, the few overheated assemblies encountered were not worth the cost of reclaiming, and were scrapped.

After braze welding, the assemblies were sent through a sequence of washing, pickling and nickel-chromium plating. Hot-water washing was all that was necessary to remove the flux. The principal processing conditions for the tubular part are summarized in the table accompanying Fig. 3.

Repair of Iron Castings

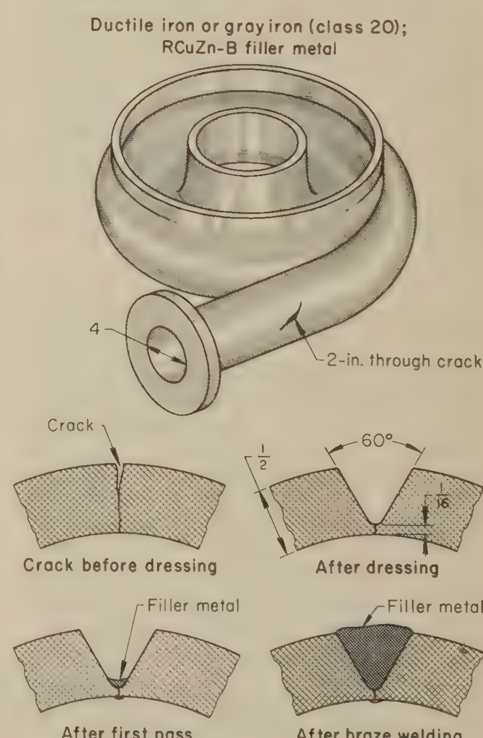
Unlike other welding processes, braze welding with copper alloy filler metals is equally effective on any type of cast iron. Peak temperatures of the base metal in braze welding can be low enough to avoid, or at least to cause very little, transformation during the heating cycle. Brittle transformation products in the heat-affected zone of the joint, therefore, can be largely prevented. The weld-metal strength is in the strength range of the gray irons, the ferritic malleable irons and the lower-strength ferritic ductile irons. Tension tests of braze welded joints have sometimes shown a disturbingly frequent occurrence of parting at the bond line, but this is generally attributed to improper cleaning, fluxing or tinning, and it emphasizes the need for care and skill.

The low temperature requirements of braze welding make the process particularly suitable for joining malleable iron. Cast iron base metal rarely needs to be preheated to more than 1000 F, and lower temperatures are often used. In fact, the base metal itself determines the correct preheating temperature; if too hot or too cold, the filler metal will not wet (or "tin") the joint. The heat added during braze welding is normally of short duration.

The principal drawbacks of braze welding as applied to cast iron are: (*a*) the color of the copper alloy filler metal does not match that of the iron; (*b*) the corrosion resistance of the weld metal differs from that of the base metal, being particularly low when the weld metal is exposed to strong alkalis; (*c*) galvanic corrosion, due to dissimilar metals, may be a problem; and (*d*) the strength of a braze weld falls off rapidly with increasing temperature, so that the service temperature of the casting is limited to 500 F max.

Braze welding is used to join cast iron to itself or to other metals for production assemblies, but it is more widely used for repairing castings worn or broken in service. In addition to its low cost, in comparison with the cost of gas welding with cast iron rods, the chief advantages of braze welding can be summarized as follows:

1 Low thermal stresses minimize the possibility of cracking in the cast iron, which is a brittle material.
2 Low peak temperatures avoid the formation of brittle transformation products encountered with other joining processes.
3 The copper alloy weld metal is sufficiently ductile to absorb most shrinkage stresses without cracking or parting at the bond.



Filler metal	⅛ in., RCuZn-B
Tip-orifice size	No. 36 drill (0.1065-in. diam)
Flame	Neutral
Preheat	1400 F, local
Postheat	None (slow cooling under insulation)

Fig. 4. Oil-soaked pump casting in which a crack was repaired by braze welding (Example 527)

4 Where preheating requirements can be met by local torch preheating, the repair can often be made in position.
5 Postheating requirements usually involve only slow cooling from the braze welding temperature.
6 Braze welding is better suited to the repair of malleable iron castings than is arc or gas welding.

The braze welding of cast iron usually requires extra care in joint preparation and cleaning. The two main considerations are the presence of graphitic carbon and the possibility of oil or other impregnation existing as a result of service. The best method of removing cracks or preparing broken edges is by chipping and abrasive blasting. Other methods of metal removal result in smearing of the graphite, which prevents bonding.

A salt bath offers the best method for cleaning cast iron (see the preceding section on Cleaning Before Braze Welding). However, smeared graphite as well as impregnations can be removed by heating the surface of the casting to a dull red heat (approximately 1200 to 1400 F). Heating the casting surface to this temperature range may cause the formation of surface oxides that prevent wetting by the filler metal; for this reason, the use of a tinning flux is helpful if heating has been used to remove graphite before braze welding.

The following example indicates the methods that were necessary for successful repair braze welding of an iron pump casting.

Example 527. Selection of Method for Repairing Oil-Soaked Pressure Castings (Fig. 4)

Centrifugal pump castings of either ductile or gray iron (see Fig. 4) were designed to pump transformer oil at 50-psi pressure. Defects, which sometimes became evident after the pump had been in operation, were difficult to repair because oil had penetrated deep into the material. The manufacturer found that, even after cutting out the defect, burning out the oil at high temperature and wire brushing the surface, neither gas welding nor arc welding produced a leaktight repair. Braze welding, however, proved successful. It was believed that some residue remained below the surface of the base metal after heating, and that in gas or arc welding, this residue caused excessive porosity during fusion of the base metal. Because the base metal was not melted in braze welding, a leaktight bond was made on the cleaned surface.

Figure 4 shows the location of a fine crack that was repaired by braze welding using the following procedure:

1 With an abrasive cutoff wheel mounted on a hand grinder, the crack was dressed out to form a 60° V-groove with a small radius at the bottom, leaving approximately 1/16-in. thickness, as in Fig. 4.
2 The inside of the pipe along the crack area was cleaned off using a rotary file.
3 The joint area was heated by an oxyacetylene torch to cherry red (approximately 1400 F), to burn off the oil.
4 The weld groove was wire brushed to remove all surface residue.
5 An oxyacetylene torch was then used to preheat the joint area to a cherry red (approximately 1400 F).
6 A 1/8-in. manganese bronze filler rod (RCuZn-B) was heated for a length of about 1 in. and dipped into a flux.
7 Heat was concentrated on the bottom of the groove until the filler metal started to wet the iron. A thin layer of filler metal was applied, penetrating to the inside of the pipe through the base metal at the bottom of the groove.
8 The remainder of the groove was filled, with the filler-metal rod being dipped into the flux as required.
9 After the joint was completed, the torch was slowly worked away from the joint so that the redness of the base metal disappeared slowly.
10 The joint area was wrapped in asbestos and allowed to cool slowly.

Other details are summarized in the table that accompanies Fig. 4.

Oxyacetylene Welding of Cast Irons

*By the ASM Committee on Welding of Cast Irons**

OXYACETYLENE welding is widely used on gray iron, to a smaller extent on ductile iron, and only to a minor extent on malleable iron. Cast iron filler metal is melted together with the base metal to form the joint.

An oxyacetylene flame has a maximum temperature of about 6000 F, which is several thousand degrees less than that of a welding arc. Gas welding is therefore slower, and results in greater heat input and wider heat-affected zones than those produced by arc welding. For this reason, high preheats of 1100 to 1200 F are generally used for gas welding of cast irons. However, for local repairs and small unrestrained castings, lower preheat temperatures (often as low as 800 F) may be used. Depending on the mass, composition and structure of the casting, postheating requirements vary from slow cooling to complete stress relief (1150 F) to full annealing (1650 F). Because of higher preheat, and thus lower cooling rates, gas welding produces less hardening in the heat-affected zone than does arc welding. Cast irons that are preheated, welded and slow cooled are readily machinable (important in much repair work).

Like the castings themselves, welds in gray iron castings have nil ductility. In a series of tests, joints in class 30 gray iron that were gas welded with RCI rods had a somewhat lower average tensile strength than the same joints gas welded with RCI-A rods or shielded metal-arc welded with ENiFe-CI electrodes. In these tests, the castings were preheated to 400 to 500 F for arc welding, and to 1100 to 1200 F for gas welding, and all welds were cooled slowly under insulation. In spite of the greater heat input and the high preheat temperatures used, welders skilled in gas welding of cast iron produced results comparable to the best arc welded joints.

In the same tests, joints in malleable iron that were gas welded using the ductile iron rod RCI-B were not of good quality. The poor results were attributed to: (*a*) the low melting point of the RCI-B rod (200 to 300 F lower than that of the base metal), and (*b*) hardening of the weld deposit, together with the reversion to white iron that takes place in the heat-affected zone.

Gas welding is not recommended for joining of malleable iron (see the section on Welding of Malleable and White Irons, on page 586).

Good results have been obtained in gas welding ferritic ductile iron with ductile iron rods. In production welding, however, the speed of gas welding cannot compare with that of arc welding. In addition, welds deposited by gas welding with cast iron rods usually are less machinable than nickel or nickel-iron welds deposited by arc welding.

Porosity, which is a common problem in gas welding, can be minimized by using a slightly reducing flame.

As a general practice, oxyacetylene welding has been used on cast irons for the following purposes:

1 Repair of minor casting defects in gray iron (see Example 528) and ductile iron. Minor surface blemishes in malleable irons are sometimes repaired; generally, however, oxyacetylene welding of malleable iron is avoided whenever possible.
2 Repair of service-incurred wear and damage (Example 529), mostly on gray and ductile irons.
3 Production of gray and ductile iron weldments involving either two parts made of cast iron, or one of cast iron and one of another metal (usually steel).

Repair of Casting Defects. The most common application of welding to cast iron is the repair of rough gray iron castings. Although the majority of this repair work is done by oxyacetylene welding, some is done by arc welding (see page 235 in the article on Arc Welding of Cast Irons). If repair welding is confined to correction of small defects that affect only the appearance of the casting, inferior mechanical properties and machinability of the weld are of no consequence. The defect must be in an unstressed area that requires no machining and, as a rule, should not extend through the section. Typical defects include sand holes, porosity, washouts, cold shuts, and shift.

Castings that have defects resulting from machining errors also can be repaired by oxyacetylene welding, provided that the heat of welding does not cause distortion. Usually, arc welding is preferred to oxyacetylene welding for correction of machining errors, because arc welding is faster, has a lower heat input (and therefore causes less distortion), and produces welds with adequate properties. Good color match of weld and base metal generally is an additional requirement.

Reclaiming defective castings by repair welding is common practice. One

*For committee list, see page 235.

Table 1. Chemical Compositions of Cast Iron Filler Metals Used for Oxyacetylene Welding of Cast Iron (AWS A5.15-69)

Classification	C	Si	Mn	Ni	Mo	P	S	Ce
RCI	3.25-3.50	2.75-3.00	0.60-0.75	Trace	Trace	0.50-0.75	0.10 max	...

foundry has reported that the average cost of repairing leaks in pressure castings was 9% of the selling price of the castings. The repairs were made by oxyacetylene welding, using a cast iron welding rod, to salvage castings that would otherwise have been scrapped. The 9% repair cost was allocated as follows:

Material 2.5%
Labor 1.5
Burden, including gas, electricity and amortization 5.0

Repair of Damaged Castings. Iron castings that have become cracked, broken or worn in service are regularly repaired by oxyacetylene welding. Braze welding (see the article on Oxyacetylene Braze Welding of Steel and Cast Irons, which begins on page 579) is used in many applications because of its simplicity and low preheat requirements and because color match is seldom important in such repair.

If welding must be done under adverse conditions, extra care and attention to procedural detail are required. Because repair of damaged castings often is a major welding operation, in that a considerable mass of base metal is subjected to high temperatures, preheating is required. A temporary oven around the part or a means of providing localized heating may be needed, depending on size and shape of the part, the required temperature, and duration of heating. (See Example 529, which describes an application in which gas welding was used in preference to braze welding for repairing a cracked press frame.)

Repair of Worn Castings by Hard Facing. Oxyacetylene welding is often used to repair (build up by hard facing) specific areas of worn gray or ductile iron castings. Malleable iron castings are not well suited to repair by hard facing.

Arc and braze welding are also used for this application; the choice among the three processes depends largely on service requirements and the equipment available. If the properties obtained are acceptable, braze welding is the logical choice, because the casting is far less likely to crack than when arc or oxyacetylene welded. The choice between arc and oxyacetylene welding for repairing worn castings by hard facing usually depends on the equipment available. Similar results can be obtained with both processes (see the section on Hard Facing on page 244, in the article on Arc Welding of Cast Irons).

The cost of repairing worn castings must be weighed against the cost of replacing them. Consideration must be given to the cost of building up cast iron, a relatively cheap material, with costly hard facing alloys.

In practice, however, there are cost considerations other than just the price of the casting; delays in getting replacement castings, and downtime for replacing a casting in a machine, are often more important. Repair by hard facing eliminates procurement delays, and saves downtime by prolonging casting life. A casting that has been hard faced by welding often lasts two to five times as long as the original casting.

Mill-roll journals, rolling-mill guides, wire-spinning rolls, and cast components of mills that process abrasive materials like cement and clay products are typical applications of repair by hard facing.

The overlay (hard facing) material applied to castings by oxyacetylene welding usually contains at least 3.0%, and more often 4.0 to 5.0%, carbon — which usually equals or exceeds the carbon content of the base metal. In addition to having high carbon contents, most hard facing materials also have high alloy contents. Most hard facing materials are proprietary alloys; three typical ones have nominal (iron-base) compositions, as follows:

3.9 C, 32.0 Cr, 6.0 Mo
4.1 C, 16.0 Cr, 2.0 Ni, 8.0 Mo, 1.0 V
4.3 C, 16.0 Cr, 6.0 Ni, 8.0 Mo

For other compositions of hard facing alloys, see Table 2 on page 154 in the article on Hard Facing by Arc Welding. Hard facing alloys such as the three listed above are available in rod form for welding with oxyacetylene.

Preheating the casting prior to welding the overlay is mandatory to prevent cracking. For castings having reasonably uniform sections, preheating to 650 to 700 F is sufficient; but for castings having a wide variation in section thickness, preheating in the range of 1100 to 1200 F is generally recommended. Time at preheating temperature should be sufficient to ensure that the casting has been uniformly heated.

Postheating is not necessary, but the welded casting must be cooled slowly. In preferred practice, the welded casting is immediately placed in a furnace maintained at or near the preheating temperature used, and then is cooled in the furnace. If a furnace is not available, the welded casting should be buried immediately in an insulating material such as lime or spent carburizing compound, and be allowed to remain buried until it has cooled to near room temperature.

Production of Assemblies. Design limitations and production problems sometimes can be overcome by welding iron castings to other iron castings or to steel. Some form of arc welding is usually preferred because it is fast, but oxyacetylene welding is also used.

Preparation of Castings

If a casting to be repaired has been in service, preparation of the casting for welding requires, in addition to edge preparation, the removal of surface contaminants. Oil, grease and paint should be removed with solvents, commercial cleaners or paint removers as required. Impregnated oil or other volatile matter can be eliminated by heating the casting or weld groove to approximately 900 F (dull red heat) for about 15 min and then wire brushing, grinding or rotary filing to remove the residue. Casting skin on surfaces adjacent to the joint area should be removed by grinding, chipping, shot blasting or rotary filing. Defects such as porosity, inclusions and cold shuts should be gouged out and the bottom of the cavity should be well rounded rather than V-shape.

Completely broken sections should be dressed to form a single-V joint, with a 1/16-to-1/8-in. root face to align the parts. Gas welding requires a V-groove with an included angle of 60 to 90°, to permit proper manipulation of the torch and welding rod. For heavy sections, a double-V joint should be prepared whenever feasible, with a root face at or near the center.

Preheating

By decreasing the rates of heating and cooling of the weld metal and adjacent base metal, preheating minimizes the formation of brittle microstructures in the zone around the weld, and thus reduces stresses that might cause cracking immediately after welding and in service. Softer, less brittle microstructures are obtained with high rather than low preheat temperatures. Recommended preheats are discussed in the individual sections of this article devoted to gray and ductile irons.

To ensure that the preheat temperature is maintained throughout the welding operation, it may be necessary to insulate the heated casting. Heat input from welding must not be permitted to increase the interpass temperature above the maximum preheat temperature, or welding must be stopped until the temperature drops to the preheat range. Temperature should be measured by contact pyrometers or temperature-indicating crayons at or near the weld zone and at one or more other places as required. (See also page 236 in the article on Arc Welding of Cast Irons, in this volume, for additional information on preheating.)

Postweld Heat Treatment

Postweld heat treatment may be either stress relieving or full annealing. Stress relieving at 1150 F and then furnace cooling to 700 F or lower is recommended whenever feasible. Full annealing at 1650 F produces greater softening of the weld zone and more nearly complete stress relief, but it also lowers the tensile strength of all but the softest irons.

Welding Rods

Cast iron rods used in the welding of cast iron should contain enough carbon and silicon to allow for losses of these elements during welding. The silicon content of the filler metal must be high enough to permit carbon to precipitate as free carbon during solidification and to promote a soft, machinable matrix as the weld cools to room temperature. Chemical compositions of

cast iron filler metals used for oxyacetylene welding of cast iron are given in Table 1.

Rods made of cast iron usually are 24 in. long and ¼ in. square, although rods ⅛ to ½ in. square are available.

The RCI filler metal and a number of proprietary rod compositions are used for welding gray irons of classes 20 to 35 (20,000 to 35,000 psi tensile strength). Gray irons that have tensile strengths of 35,000 to 40,000 psi can be welded with RCI-A filler metal, which is similar to RCI but also contains 1.20 to 1.60% nickel and 0.25 to 0.45% molybdenum. Many proprietary rods contain chromium, nickel, molybdenum, copper, or vanadium, either singly or in combination, to produce high-strength welds; carefully controlled procedure is required with these rods to avoid obtaining a hard weld deposit.

Two basic types of welding rods have been successfully used for welding ductile iron: RCI-B, which is generally higher in carbon and silicon content and lower in manganese than the gray iron rods and contains cerium as a nodularizing agent, and proprietary rods in which magnesium is used as the nodularizing agent.

Fluxes

A flux is required in gas welding of cast iron to increase the fluidity of the fusible iron-silicate slag, as well as to aid in the removal of the slag. Fluxes for gray iron rods are usually composed of borates or boric acid, soda ash, and small amounts of other compounds such as sodium chloride, ammonium sulfate and iron oxide. A mixture of equal parts of boric acid and soda ash, 2% ammonium sulfate and 15% powdered iron makes a satisfactory flux.

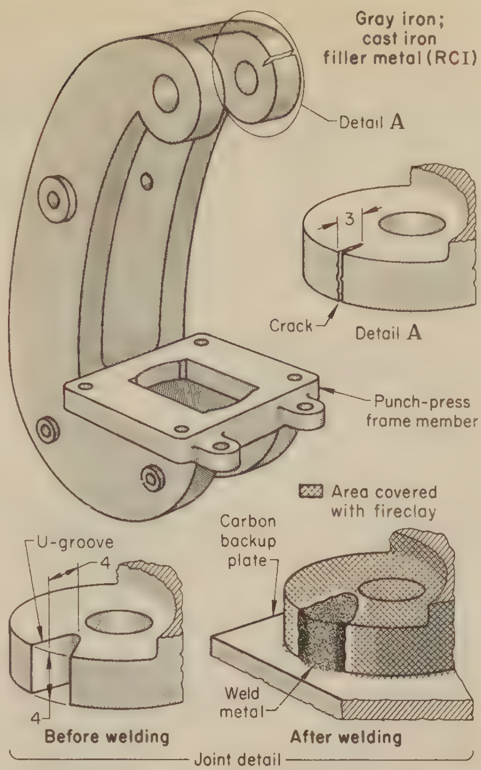
Fluxes suitable for welding ductile iron with a ductile iron rod are similar to those used for welding gray iron, but are formulated to produce a slag with a lower melting point. Some proprietary fluxes contain inoculants.

Welding of Gray Iron

Gas welding of gray iron generally is done for repair, but also can be done for production of simple assemblies. The cavity is first prepared for welding by the usual methods (see the section on Preparation of Castings) and then ordinarily is tested by liquid-penetrant or magnetic-particle inspection to ensure freedom from defects.

The casting preferably is preheated to 1150 F in a furnace and then covered with asbestos cloth, exposing only the cavity to be welded. If a furnace is not available, the casting can be covered with asbestos cloth and locally heated by gas flame.

A high-velocity torch that will produce a concentrated flame pattern, similar to that used for welding mild steel, should be used. The cavity surface is dusted with a thin layer of flux, the heated rod is dipped in flux and positioned in the cavity, and both are heated with an oxyacetylene torch adjusted for a neutral or slightly reducing flame. The rod and a small area of the cavity soften under the flame, and as



Filler metal	¼-in.-square rod, RCI
Flux	Proprietary(a)
Oxygen pressure	90 psi
Acetylene pressure	17 psi
Tip size	No. 16 drill (0.177-in. diam)
Preheat	1200 F
Postheat	1200 F for 6 hr
Welding time (total)	16 hr

(a) Mainly sodium borates and carbonates

Fig. 1. Repair of a large crack in a gray iron punch-press frame by gas welding under conditions given in table (Example 529)

the rod melts off and combines with the base metal, the torch and rod are slowly moved along the cavity. The flame should be directed at the bottom of the cavity with the tip held ¼ to ⅛ in. from the metal until a molten puddle up to 1 in. long begins to form. The torch is moved from side to side until the walls of the cavity start to melt into the puddle. This process is continued until the entire cavity is filled with weld metal ¹⁄₁₆ to ⅛ in. thick. It is advisable to play the welding flame back over the previously deposited metal to retard its cooling rate, to reduce residual stress, and to permit escape of entrapped gas.

Postweld stress-relieving is recommended, particularly for complex castings or where accurate machining will follow. The casting should be placed in a furnace that is at the same temperature as the casting, immediately upon completion of welding, and gradually heated to 1100 to 1200 F for one hour per inch of thickness; it may then be cooled to 500 F or below at a rate no faster than 50 F per hour. When the welded casting is not stress relieved, it should be cooled slowly either in a furnace or by covering it with asbestos paper, sand, or some other insulating material.

When class 30 irons are preheated to 1100 to 1150 F before gas welding, some fine pearlite and ferrite are present in the final weld metal and in the heat-affected zone; weld tensile strength approaching 30,000 psi and hardness less than 200 Bhn can be obtained. When class 40 irons are gas welded under similar preheat conditions, higher proportions of fine pearlite, less ferrite, and some cementite are present, and weld strength may reach 35,000 psi, with hardness as high as 200 Bhn. Although higher-strength irons containing chromium and molybdenum have been welded, welding rods compatible with these irons are not readily available. When specially made welding rods were used experimentally, weld-metal tensile strength up to 45,000 psi was obtained, but carbide formation, which caused cracking, was difficult to control. Welding generally is not attempted in gray iron stronger than class 50, because of the high probability of cracking.

Difficulty in machining is seldom encountered if high preheat and interpass temperatures are used. Class 40 irons usually can be gas welded to a hardness of 200 Bhn or less in weld metal and heat-affected zone. Cast iron welding rods provide good color match.

More welding of cast iron is done in foundry repair of defects in new castings than in any other type of application. Processes most frequently used are gas welding and shielded metal-arc welding. The example that follows describes a production-line repair setup that is typical of automotive foundries.

Example 528. Repair of Defects in Automotive Engine Blocks

In an automotive-engine foundry, defects in gray iron engine-block castings were repaired by gas welding at a rate of 16.9 castings per hour. The castings weighed about 225 lb each, measured 22 by 18 by 10 in., and had section thicknesses varying from approximately ³⁄₁₆ to ⅝ in. The welding was done to seal leaks and to repair surface imperfections that had been caused by sand inclusions. Repairable castings were moved by conveyor through six operations.

After shakeout, in order that defective areas would be visible after preheat, castings were inspected and marked for repair before being conveyed to a gas-fired tunnel furnace, where they were heated slowly to 1200 F and soaked for a minimum of 30 min. A cutting torch was then used for thoroughly cleaning out and preparing defective areas for welding.

Next, the cavities were filled in by oxyacetylene welding, using a ¼-in. cast iron rod for filler metal. Both cleaning and welding had to be done rapidly, since no welding was permitted if the casting temperature dropped below 850 F. Similarly, no welding was done if the temperature of the preheat furnace fell below 1150 F, or that of the postheat furnace fell below 1000 F. After welding, castings were conveyed to a furnace, where they were heated to 1050 F, and then were furnace cooled to 600 F over a period of at least 45 min. The final operation consisted of removing the flux deposit and grinding the weld surface flush.

For the repair of a cracked punch-press frame as described in the following example, gas welding was selected over braze welding for reasons of strength and appearance.

Example 529. Repair of a Cracked Punch-Press Frame (Fig. 1)

When a crack appeared in the frame of an old punch press (see Fig. 1), gas welding was selected over braze welding as the

repair method. All that was known of the base metal was that it was cast iron; it was assumed to be gray iron, probably of class 30 or 40.

When chipped out, the crack was 3 in. deep. It was enlarged to form a U-groove 4 in. deep with a 4-in. opening. The frame member was laid on its side and firmly braced, and the area near the weld zone was packed in fireclay (Fig. 1). The weld area was then preheated to 1200 F with a heating torch. Welding was done with a heavy-duty oxyacetylene torch fitted with a large welding tip, using cast iron filler metal and a carbon plate for backing. During welding, heat had to be applied from time to time to maintain an interpass temperature of about 1200 F. After welding, the frame member was stress relieved by being heated to 1200 F and held for 6 hr. Additional welding conditions are given in the table that accompanies Fig. 1.

Welding of Ductile Iron

Oxyacetylene welding is often used for the repair of defects in ductile iron castings. It has also been used successfully for hard facing of specific areas on castings for the purpose of increasing resistance to abrasion or corrosion (see Example 540 in the article on Hard Facing by Oxyacetylene Welding, in this volume). Oxyacetylene welding of ductile iron has been most successful using a ductile iron rod.

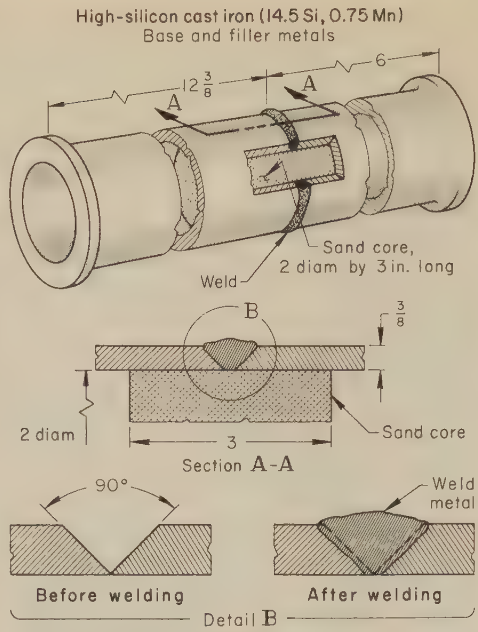
The repair of ductile iron castings is complicated by the fact that the only way to obtain graphite in nodular form in the weld deposit is to cause it to precipitate from the liquid in that form. Processes have been developed to cause nodularization by introducing magnesium or cerium, or both, into the weld zone by means of a special cast iron filler rod or a special flux. Filler metal RCI-B should be used for welding ductile iron.

Magnesium and cerium are carbide formers, and consequently must not be present in amounts beyond those required for nodularization. If these elements are present in excessive amounts, a postweld ferritizing anneal is necessary to restore ductility to the weld area; annealing reduces the strength of pearlitic irons and causes distortion of machined surfaces.

Joint preparation and joint cleanness require the same careful attention and the same procedures described earlier for welding gray iron. Preheating practice and interpass temperatures are essentially the same for welding ductile iron as those described in the foregoing for gray iron.

In welding ductile iron, a reducing flame should be used to minimize oxidation of the volatile nodularizing elements contained in both the base metal and the welding rod. The welding tip should be a type that produces a concentrated flame pattern. The weld area or the complete casting is first preheated to a dull red and flux is applied to the bottom of the weld groove. Heat is directed at the bottom of the weld groove until a puddle begins to form. Walls adjacent to the weld groove are then softened to blend into the puddle. It is recommended that the length of the molten puddle be limited to one inch.

A major problem in the welding of ductile iron is the complete loss of ductility in the heat-affected zone.



Filler metal	Same as base metal(a)
Flux	50% lime, 50% sodium bisulfite
Backing	Solid cylindrical sand core
Flame adjustment	Oxidizing
Welding position	Horizontal rolled
Number of passes	Two
Preheat	Furnace, 1600 F
Interpass temperature	1000 to 1650 F
Postheat	Furnace, 1600 F for 2 hr, furnace cool
Fixtures	Clamping jig, turning rolls

Welding of Malleable and White Irons

The effect of oxyacetylene welding on malleable iron is to create a wide heat-affected zone of white iron, the material from which the malleable iron was originally produced by applying a malleablizing heat treatment. Because of the hardness and brittleness of the white iron, base-metal properties are lost and the joint is prone to cracking. The hardened zones in either ferritic or pearlitic malleable iron can be reduced by annealing, but only by processing the casting through a special heat treating procedure for which the original foundry is best equipped.

Oxyacetylene welding is used in the foundry repair of small defects on rough castings. The repair is done while the casting is in the white iron condition, before malleablizing. White iron welding rods are used, which are cast by the foundry to match the base-metal composition, after allowing for constituent losses in deposition. Repair procedures are the same as for gray iron except that, after welding, the casting is given its normal malleablizing heat treatment.

Braze welding, using a copper alloy welding rod, is a more satisfactory method of obtaining relatively strong, machinable joints in malleable iron. Because the base metal is not melted in braze welding, peak temperatures are relatively low, and there is very little hardening in the heat-affected zone. Color match between the weld and the base metal is poor, however, and the service temperature of the casting is limited to about 500 F. Details of the process are given in the article on Oxyacetylene Braze Welding of Steel and Cast Irons, which begins on page 579 in this volume.

Gas metal-arc welding with bare-wire steel electrodes has been used in joining malleable iron where end uses do not require full base-metal strength properties. This process produces high peak temperatures, which are of short duration because of high welding speed. Heat-affected zones are therefore narrow. This process is discussed briefly on page 243 in the article on Arc Welding of Cast Irons, in this volume.

Welding of Corrosion-Resistant Cast Irons

Corrosion-resistant cast irons usually are identified as high-silicon, high-chromium or high-nickel irons, specifications for some of which permit welding for repair of minor casting defects. Weld deposits must usually duplicate base-metal compositions, but filler metals may not be generally available. The example that follows gives details of the special procedure that was successfully used by one manufacturer for assembly welding of corrosion-resistant high-silicon cast iron pipe.

Example 530. Assembly Welding of High-Silicon Cast Iron Pipe (Fig. 2)

High-silicon cast iron pipe, used for transporting liquids corrosive to steel, was normally manufactured in diameters ranging from 1 to 8 in. and in standard lengths of 3, 4 or 5 ft, depending on diameter. Standard pipe lengths were cast with beaded ends to permit coupling with split flanges, gaskets and bolts. Nonstandard lengths were made to order by welding together two pipe ends of suitable length. The manufacturer of this alloy iron found that a special gas welding procedure was the only practical method of obtaining a satisfactory weld.

Figure 2 shows the weld joint in an 18⅜-in. length of 2-in. pipe, normally supplied in 4-ft lengths. The sequence of operations for welding this pipe was as follows:

1. Grind both joint edges to 45° bevel.
2. Align parts in a clamping fixture and insert a 3-in.-long sand core to straddle the joint to be welded.
3. Preheat to 1600 F in a furnace.
4. Adjust oxyacetylene torch for oxidizing flame. (Extensive trials with reducing flames resulted in poor fusion and cracking, apparently because sufficiently high temperature could not be attained.)
5. Remove from furnace and tack weld in three places, using a high-silicon cast iron welding rod of the same composition as the base metal, together with a lime-base flux.
6. Place on turning rolls and weld in two passes, using the same rod and flux as for tacking. Place sheet insulation over the pipe, leaving opening over weld area for access. Maintain interpass temperature between 1000 and 1650 F.
7. Return to furnace for 2 hr at 1600 F; cool in the furnace with doors shut and burners off.
8. Inspect welds visually for cracks and other defects.
9. Test hydrostatically at 75 psi.

Welds produced by this method had the same corrosion resistance as the base metal. By welding special pipe lengths to order, inventory requirements were reduced and pattern alterations were avoided. Conditions for gas welding are given in the table with Fig. 2.

Hard Facing by Oxyacetylene Welding

*By the ASM Committee on Hard Facing**

OXYACETYLENE WELDING is used in many applications requiring build-up and hard facing. The welding equipment used is simple and versatile, and capital investment costs are low in comparison with those for arc welding. (For information on the use of arc welding for hard facing, including a comparison with the oxyacetylene process, see the article on Hard Facing by Arc Welding, page 152 in this volume, particularly Tables 3 and 4.)

Limitations. Hard facing by manual oxyacetylene welding requires a high degree of welder skill to obtain smooth, high-quality deposits, since both the welding rod and the torch flame have to be separately manipulated. The speed of welding is low compared with that of arc welding, and low deposition rates often preclude the use of oxyacetylene welding for hard facing applications on large components that require large quantities of facing alloy, unless automation of the operation is warranted by configuration of the surface and number of identical parts.

Major Applications. Oxyacetylene welding is best suited to hard facing applications in which the surface area to be faced is small. Thus, for facing steam valves, automotive and diesel-engine valves, cutter blades for wood and plastic, chain saw bars, and plowshares and other agricultural implements, it is often the most satisfactory process. It can be easily employed in the field. Broken edges on gear teeth, mismatched surfaces of machinery components, and parts made of nonferrous alloys, such as admiralty brass or Monel, can be built up with metal similar in composition to the base metal, or with a different metal.

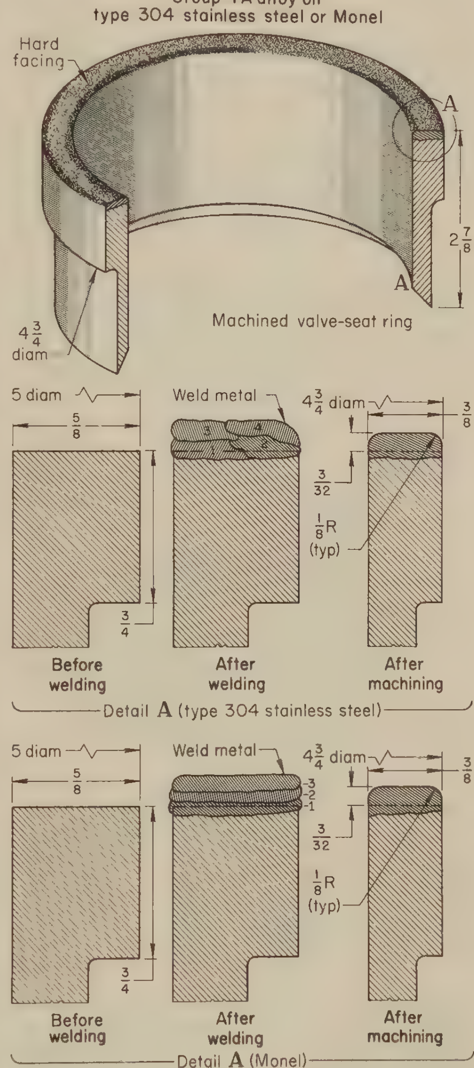
Principles of Operation

Supplies of oxygen and of acetylene, regulators, a welding torch, and welding rods are the primary requirements for hard facing by oxyacetylene welding. The factors that contribute to the success of the application are appropriate choices of gas mixture, gas pressure and velocity, and flame characteristics. The article on Gas Welding, page 565 in this volume, describes the equipment used for the control of these process variables.

Hard Facing Alloys

Most hard facing alloys can be applied by oxyacetylene welding. For the classification and compositions of these alloys, see Tables 1 and 2 in the article on Hard Facing by Arc Welding, which begins on page 152 in this volume. Choice of a specific alloy depends primarily on the application (see the article on Selection of Hard Facing Alloys, which begins on page 820 in Volume 1 of this Handbook).

Most hard facing alloys are available in different forms. Many of the more ductile alloys are available in the form of coiled wire. Those that are too brittle to coil are supplied as straight lengths of rod. Some alloys come in powder form and are applied by spraying, using a specially designed torch that incorporates a powder dispenser. Carbide materials are often supplied as granules contained in a metal tube (usually of low-carbon steel); the tube portion melts, thus acting as a matrix to embed the carbide on the work-metal surface.



Weld type	Hard facing
Thickness of hard facing overlay after machining	3/32 in.
Hard facing alloy	1/8 and 1/4-in.-diam 4A(a)
Gas pressure:	
Acetylene	5 psig
Oxygen	15 psig
Tip-orifice diameters	0.025 to 0.070 in.
Preheat	(b)

(a) Cobalt-base alloy with 28.5 Cr, 4.5 W, 3.0 Ni, 1.10 C. (b) For stainless steel rings, furnace preheat at 900 to 1000 F for 1 hr. For Monel rings, furnace preheat at 1150 to 1250 F for 1 hr, and torch heat at 1500 to 1650 F for no more than 30 minutes. Interpass temperature for Monel was 1500 to 1650 F.

Fig. 1. Valve-seat ring made of stainless steel or Monel, showing hard faced area, preweld dimensions, bead sequences and machined dimensions (Example 531)

Cleaning and Fluxing

Before the hard facing operation begins, the base-metal surfaces are thoroughly cleaned.

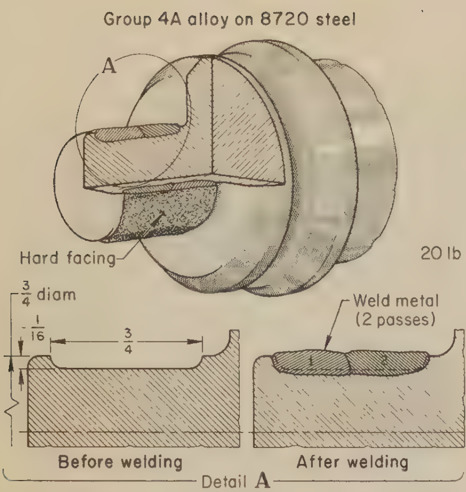
For hard facing of steel, a flux is seldom required if the surface is clean and dry, but flux may be required if the surface is contaminated and cannot be cleaned easily. For hard facing cast iron, a flux is commonly used.

If impurities are present on surfaces of the work metal, or if an excessive amount of oxide is produced in heating (usually, a neutral or reducing flame is used), it may be necessary to dislodge the solid contaminants by prodding or rubbing with the welding-rod tip. Oxide trapped beneath the hard facing overlay can react with carbon in the hard facing alloy to produce a gas and cause porosity. Hard facing alloys usually contain a deoxidizer that will control a moderate amount of oxidation.

Operating Procedures

Preheating (if used) is done after cleaning. The area of the workpiece to be hard faced is then heated to a red heat with the torch, even if preheating was used. For hard facing with cobalt-base alloys, the torch gas-inlet valves are adjusted to obtain an excess-acetylene flame having a blue envelope, or feather, about three times the length of the bright inner cone. This type of flame, called a "3×-feather" flame, is carburizing and helps to reduce oxides. It also adds carbon to the base-metal surface as the temperature rises, thereby lowering the melting point of the surface. For facing with nickel alloys, a neutral 2×-feather flame is commonly used. When melting begins, the surface glistens and appears watery, a condition known as "sweating". As soon as base-metal melting begins, a drop of the hard facing alloy (which has been preheated by the edge of the flame) is melted off. The drop will usually blend immediately with the sweating zone and will spread. More hard facing alloy is added as needed by melting drops from the rod, as the wetted area is carried forward by the heat of the flame. This procedure continues until the area to be hard faced is fully covered with hard facing alloy.

*For committee list, see page 152. Several of the examples in this article were contributed by members of other Metals Handbook welding committees.



Weld type	Hard facing
Thickness of hard facing overlay after grinding	1/16 in.
Hard facing alloy	1/4-in.-diam group 4A(a)
Gas pressure:	
Acetylene	15 psig
Oxygen	30 psig
Tip-orifice diameter	0.0935 in.
Oxygen flow	15 cfh
Preheat	600 F(b)
Production time	0.0599 hr per piece(c)
Cost Items	
Torch and related equipment	$95.00
Hard facing alloy, per pin	$0.47
Acetylene, per pin	$0.0041
Oxygen, per pin	$0.02

(a) Bare cast rod, 12 in. long. (b) Heating time was 2½ minutes, using natural-gas burners. (c) In lots of 100 pieces.

Fig. 2. Rotary rock-bit friction pin, showing hard faced areas on periphery (Example 532)

The procedure described in the preceding paragraph is subject to minor variations for particular applications.

Selection of hard facing alloy, gas mixture and flow rate, and operating procedure depends mainly on the base metal being hard faced, the properties and quality desired in the deposit, and the service conditions of the part. In the next example, a change in the base metal necessitated a change in hard facing procedure, although the same hard facing alloy was used.

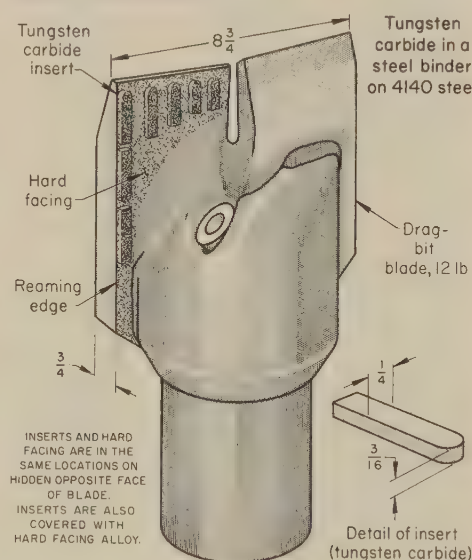
Example 531. Change in Hard Facing Procedure With Change in Base Metal From Stainless Steel to Monel (Fig. 1)

When made of type 304 austenitic stainless steel, valve-seat rings such as that shown in Fig. 1 were successfully hard faced with a cobalt-base group 4A alloy, using manual oxyacetylene welding and the procedure described below. When the valve-seat rings were made of Monel, the original procedure no longer produced acceptable deposits and had to be revised.

Type 304 Stainless Steel Rings. Valve-seat rings were machined, cleaned with acetone, preheated in a furnace at 900 to 1000 F for a minimum of 1 hr, and wire brushed before hard facing. A small area on the base-metal surface was then heated to the sweating condition, using a reducing flame. The temperature attained was high enough to ensure that sweating did not disappear when the torch tip was raised slightly. The end of the hard facing rod was then inserted into the flame and allowed to melt and flow over the sweating area. The first layer (tinning layer) was kept as thin as possible, and puddling was minimized to prevent excessive dilution with the base metal. At the end of each pass, the torch was raised with a spiral motion, which resulted in a heat gradient that allowed solidification to progress from the base metal to the surface of the deposited layer. At least two layers of hard facing alloy were applied to ensure a minimum thickness of 3/32 in. after machining. The two layers were applied in four passes, as shown in Fig. 1. Dilution of hard facing alloy with base metal was low, and liquid-penetrant tests indicated no weld cracking.

Monel Rings. When the procedure described for hard facing type 304 stainless steel valve-seat rings was used for Monel rings, difficulty was encountered in depositing the weld metal, porosity occurred in the hard facing, and the base metal cracked. The normal hard facing technique was unsuccessful because direct flame impingement (neutral or reducing) on the surface to be hard faced did not result in deposit flow. Therefore, the hard facing was deposited by using a slightly reducing flame to melt a drop of hard facing alloy onto the surface and then heating this puddle (rather than the surface) by direct contact with the hot inner cone of the flame throughout deposition. Hard facing alloy was fed to the puddle as rapidly as it would melt and flow. Three single-pass layers were deposited on the valve-seat ring, as shown in Fig. 1. After hard facing, the rings were cooled slowly in powdered asbestos.

Base-metal cracking was prevented by using preheating temperatures (1500 to 1650 F) that were higher than the hot-short range for Monel. Holding in this preheat range for no more than 30 minutes ensured against a decrease in room-temperature tensile properties.



Weld type	Hard facing
Thickness of hard facing overlay:	
Reaming edge	1/8 in.
Face of blade	1/16 in.
Hard facing alloy	Tungsten carbide tube metal(a)
Cast inserts	Tungsten carbide(b)
Gas pressure:	
Acetylene	15 psig
Oxygen	30 psig
Tip-orifice diameter	0.1285 in.
Preheat	900 F, or higher, in a furnace
Production rate	1.1 blades per man-hour
Cost Items(c)	
Torch and regulators	$250.00
Carbide inserts, per blade	$5.00
Tube metal, per blade	$7.00
Acetylene and oxygen, per blade	$2.65

(a) 60% tungsten carbide granules, 40% steel tube binder. (b) 4.0 to 4.5 C, 18.0 to 20.0 Co, 75.0 to 77.0 W. (c) Approximate.

Fig. 3. Two-way drag-bit blade, showing locations of hard facing overlay and cast inserts (Example 533)

The same torch tip-orifice sizes (0.025 to 0.070-in. diameter) were used for both procedures, but a 2× to 3×-feather flame was used for the stainless steel and a 1½× to 2×-feather flame for the Monel. Both stainless steel and Monel rings were inspected by the liquid-penetrant method after machining. Surfaces showing linear indications, or rounded indications more than 1/64 in. in diameter, were not acceptable. Additional processing details are given in the table with Fig. 1.

Manual Oxyacetylene Welding

Hard facing by manual oxyacetylene welding requires good coordination of rate of heat input and speed of welding, so that the flame can properly position and shape the weld bead. To obtain the temperature conditions needed for hard facing, preferential heating of the base metal or of the hard facing rod may be required. The welder must exercise control over the temperature at the weld zone, the deposition rate, and the nature and shape of the deposit. Several examples of hard facing using manual oxyacetylene welding are presented in this section.

Components of Oil-Field Equipment. The four examples that follow describe the successful application of hard facing to oil-field equipment components using manual oxyacetylene welding (see also Example 542, in which hard facing of rotary rock-bit bearings was mechanized).

Examples 532 to 535. Hard Facing of Parts for Oil-Field Equipment, Using Manual Oxyacetylene Welding

Example 532 — Rotary Rock-Bit Friction Pin (Fig. 2). Rotary rock-bit friction pins made of 8720 steel were coated with an abrasion-resistant hard facing alloy in accordance with the following procedure. A groove, 1/16 in. deep and 3/4 in. wide, was machined around the pin (see Fig. 2, Before welding), maintaining a 250-micro-in. or better surface finish on the machined areas. Next, the surface to be hard faced was washed with a solvent to remove cutting fluids and rust preventives. The pin was then preheated to 600 F in about 2½ minutes with natural-gas burners, and a hard facing of a group 4A alloy was applied to the groove, using a 3×-feather oxyacetylene flame and backhand welding. Additional processing details are given in the table that accompanies Fig. 2. Two passes were made and each bead was ended by overlapping the starting point, to allow trapped oxides to float to the surface where they could be removed by grinding. Upon completion of the hard facing operation, the pin was ground to finish dimensions, leaving a uniform deposit about 1/16 in. thick.

Example 533 — Two-Way Drag-Bit Blade (Fig. 3). Satisfactory service was obtained by hard facing of the two working surfaces on the blade of a 4140 steel drag bit with tungsten carbide tube metal, together with selective placement of cast tungsten carbide inserts, as shown in Fig. 3. Preparation for hard facing consisted in sand blasting all blade surfaces, machining the reaming edges, and preheating the blades by holding them in a furnace until a temperature of at least 900 F was attained. Welding of the inserts and hard facing alloy was done with an oxyacetylene torch equipped with a tip with a 0.1285-in. orifice. Inserts were attached by sweating them onto the surface of the blade. They and other areas of the blade, as shown in Fig. 3, were then covered with the hard facing alloy. The hard facing material was tungsten carbide granules contained in a steel tube. Tube size ranged from 1/4 to 1/8 in. in diameter. Postheating was not required.

Additional processing data and costs for equipment and consumable materials are given in the table that accompanies Fig. 3.

Example 534 — Blade-Type Stabilizer (Fig. 4). The three-blade stabilizer shown in Fig. 4, which is typical of many used in oil-field applications, was made by welding 1020 steel blades on a 4140 steel body and subsequently hard facing the surface of the blades as shown in Fig. 4. The number of blades on a stabilizer varied from three to six, and the length of the blades varied from 18 to 24 in.

Blades were prepared by machining to dimensions, welding onto the stabilizer body, and cleaning. Before hard facing, the stabilizer was preheated to 900 F, using natural-gas burners. The outer surface of each blade was hard faced with an overlay of 3/16 in. (max) of tungsten carbide tube metal (tungsten carbide granules in a steel tube), without flux, using an acetylene torch with a 0.1285-in.-diam tip orifice. Postheating was not required, and the blades were used as-surfaced, without further grinding or machining.

Additional processing conditions and approximate costs for equipment and consumables are given in the table that accompanies Fig. 4.

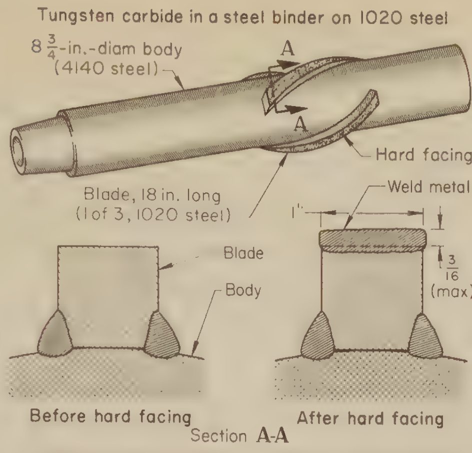
Example 535 — Junk Mill (Fig. 5). The 7¾-in.-diam junk mill shown in Fig. 5 is typical for the size range of about 3¼ to 8¾ in. in diameter. Some junk mills are much larger. Junk mills are used in oil-field operations for cutting up steel "junk" (broken and jammed tools in oil wells being drilled), and therefore it is mandatory that one side and the end of each cutting blade be hard faced to resist the extreme abrasion to which it will be subjected.

The mill shown in Fig. 5 was hard faced with tungsten carbide particles in a matrix of brass or nickel silver. Hard facing was done with an oxyacetylene torch equipped with a tip having an orifice diameter of 0.1285 in. The following processing steps were used:

1 The mill was placed in a fixture that would hold and rotate it for flat-position welding.
2 Areas to be hard faced were cleaned well.
3 A carbon mold block was clamped in position to prevent the hard facing alloy from running onto surfaces where it was not wanted.
4 The first blade was positioned. The whole area to be hard faced was preheated using a neutral flame and oscillating the flame. To remove surface oxide and inhibit oxide formation during welding, preheated surfaces were coated with a suitable flux.
5 Using a soft, neutral flame, flux-covered surfaces were pretinned with an overlay of about 1/16 in. of brass or nickel silver.
6 Employing the same neutral flame, and moving the flame evenly and smoothly over the entire surface, a group 5 (tungsten carbide) composite alloy was deposited on the pretinned surface. The composite alloy consisted of crushed tungsten carbide particles (particle size of ⅛ to ¼ in., classified by a screen) in a matrix of brass. The carbide particles were positioned while the deposit was still molten, care being taken to avoid directing the cone of the flame at the carbide particles.
7 Steps 3 to 6 were repeated for the remaining five blades.
8 The hot workpiece was wrapped in asbestos and permitted to cool slowly.

Other welding conditions, and costs for equipment and consumables, are given in the table that accompanies Fig. 5.

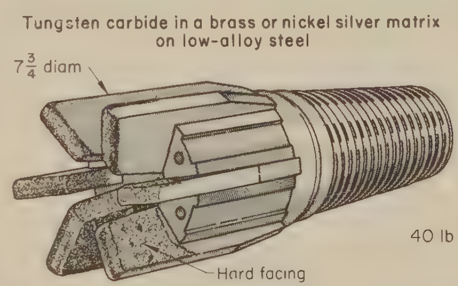
Engine Valves. Hard facing of the seating surfaces of engine valves (especially exhaust valves) by oxyacetylene welding is common practice. The process is used on new valves and for salvaging worn valves. It is applicable to relatively small valves, such as those used in small commercial engines, and to large diesel-engine valves that weigh more than 50 lb each. A procedure that proved successful for hard facing 1.892-in.-diam valves is described in the following example.



Weld type	Hard facing
Thickness of hard facing	3/16 in. max
Hard facing alloy	Tungsten carbide tube metal(a)
Gas pressure:	
Acetylene	15 psig
Oxygen	30 psig
Tip-orifice diameter	0.1285 in.
Preheat	900 F, with natural-gas burners
Production time	0.3 hr per linear foot(b)
Cost Items	
Torch and regulators	$250.00
Tube metal	$2.30(b)
Acetylene and oxygen	$0.80(b)

(a) 60% tungsten carbide granules, 40% steel tube binder. (b) Approximate, per linear foot for a 3/16-in.-thick, 1-in.-wide deposit.

Fig. 4. Three-blade stabilizer with tungsten carbide deposited on cutting blades (Example 534)



Weld type	Hard facing
Thickness of hard facing	About 1/16 in.
Hard facing alloy	Group 5(a)
Welding position	Flat
Gas pressure:	
Acetylene	15 psig
Oxygen	30 psig
Tip-orifice diameter	0.1285 in.
Preheat	300 F, with torch, using neutral flame
Production time	35 min per mill
Cost Items	
Welding equipment	$95.00
Hard facing alloy, per junk mill	$37.85
Oxygen, per junk mill	$0.20
Acetylene, per junk mill	$0.04

(a) Tungsten carbide in brass or nickel silver

Example 536. Use of Manual Oxyacetylene Welding for Rebuilding Engine-Valve Seats (Fig. 6)

The SAE EV 8 steel engine valve shown in Fig. 6 was grit blasted for removal of carbon deposits and dirt. The seat, which was to be hard faced, was then undercut in a lathe as shown in Fig. 6 (Before welding). The valve was placed on a special welding table that could be rotated by a power-driven mechanism controlled by a foot switch, and tilted for flat-position welding. The seat area of the valve head was preheated to 300 to 450 F by means of a gas torch. Using ¼-in.-diam rods of a group 4A alloy, a hard facing layer about ⅛ in. thick and ¼ in. wide was applied to the valve seat in two passes. After welding, the valves were submerged in a mica compound to ensure slow cooling. Additional processing details are given in the table that accompanies Fig. 6.

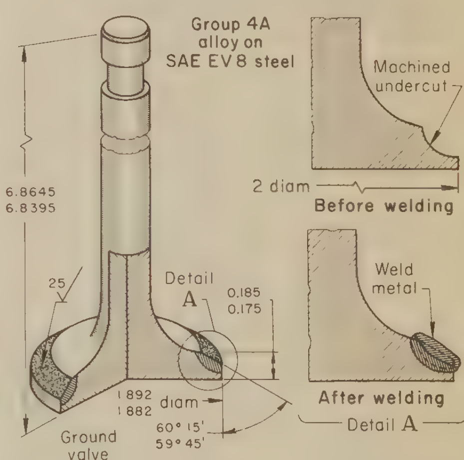
Average welding time was approximately 4 min per valve; machining before and after welding required 10 to 12 minutes. A pound of hard facing rod hard faced 20 to 25 valve seats. Cost of the special welding table was $65.

Dies and Punches for Hot Trimming. Hot trimming requires a material for the cutting edges of dies and punches that will retain its strength and sharpness at elevated temperature. Such edge properties are often obtained by hard facing, which frequently doubles the life of the die components and in some instances increases their life up to ten times. A procedure for hard facing trimming dies and punches is described in the example that follows.

Example 537. Hard Facing Edges of Hot Trimming Dies and Punches (Fig. 7)

The components shown in Fig. 7 (an A2 tool steel die and 4140 steel punch) were selectively hard faced with a group 4A alloy on the areas indicated. The hard facing alloy was applied manually with an oxyacetylene torch. A welding table and copper blocks were used to position parts for flat-position welding. The process was used on both new and worn components.

The surfaces to be hard faced were suitably grooved or recessed by milling, grinding, and boring, as required. The components were then furnace hardened and tempered to Rockwell C 45 to 50. No preheat was needed, but the surfaces to be hard faced were heated to sweating temperature by the torch used to deposit the hard facing alloy. A group 4A alloy was applied, using a 3× to 4×-feather flame. Deposit thickness varied from 1/16 to 7/32 in., depending on the thickness of the material to be trimmed and punched. After hard



Weld type	Hard facing
Thickness of hard facing	About ⅛ in. max
Hard facing alloy	Group 4A
Welding position	Flat
Preheat	300 to 450 F(a)
Production time	4 min per valve

(a) Smaller valves were heated only to ensure that moisture was removed from the surface.

The composition of SAE EV 8 is 0.53 C, 9.0 Mn, 21.0 Cr, 3.75 Ni. SAE EV 3 was also used for this type of valve; its composition is 0.20 C, 1.3 Mn, 21.0 Cr, 11.5 Ni.

Fig. 6. Engine valve that was rebuilt by hard facing the seating surface (Example 536)

facing, the surfaces were ground to close tolerances. About 12 hr was required to prepare, hard face, and finish machine one complete die set, consisting of punches, trimming die, and lower die.

The dies were used for hot trimming and punching forged track links. Service life of hard faced die components was as follows:

Die component	Number of track links
Trimming die	50,000
Small punches	15,000
Lower die	20,000
Oblong punch (not shown in Fig. 7)	30,000

About twice as many parts were trimmed and punched as would have been if die components had not been hard faced.

An application of manual hard facing for repairing cold work dies is described in Example 538.

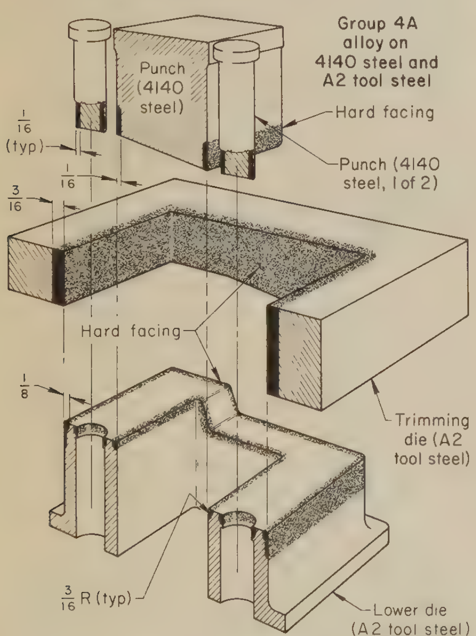
Powder Spraying

The use of an oxyacetylene torch equipped with a powder dispenser often increases the flexibility of hard facing by gas welding. The mixer section of the torch is constructed with an integral hopper for the alloy powder or a special opening into which is screwed a dispenser containing the alloy powder. Powder flow is initiated by depressing a lever on the torch handle, the powder being carried by the gases through the torch tip, where it is heated by the oxyacetylene flame.

Such a torch can be used with alloy powder alone or with powder and a hard facing rod, consecutively, or even simultaneously, as required, without stopping the operation. For filling a deep groove or a deep chipped area, common practice is to tin the area using the powder alloy, then to deposit the major portion of the hard facing alloy using an alloy rod (because it is faster), and to complete the deposit with the powder alloy. The rod and powder need not be of the same composition. When a thick deposit is required, the major portion can be laid with a rod that deposits a relatively tough metal, and the deposit can be completed by spraying on a thin layer of material of which 50% or more is tungsten carbide or another extremely hard material.

Powder spraying has proved especially advantageous in applications where a thin deposit is required (0.010 to 0.020 in. thick, for example). Powder spraying permits close control of deposit thickness, thus minimizing overdeposition, which wastes alloy and requires machining and grinding to remove the excess. Hard facing by powder-spray oxyacetylene welding is described in Examples 538, 539 and 540, in this article.

Repair of Cold Work Dies. Chipped edges of various types of cold work dies, including blanking dies, are commonly repaired by hard facing. Often this can be done without preheating or postheating the die, and therefore the die is out of service for a minimum length of time. The powder-spraying method of oxyacetylene welding described in the example that follows proved successful in one shop for repairing dies used for blanking sheet steel for automotive parts.



Weld type	Hard facing
Thickness of hard facing	1/16 to 7/32 in.
Hard facing alloy	Group 4A
Welding position	Flat
Gas flow:	
Acetylene	16 to 24 cfh
Oxygen	15 to 22 cfh
Preheat	(a)
Production time	12 hr per die set(b)

Cost Items

Hard facing alloy	6 to 7 lb at $6.12 per pound
Equipment for one welder	About $380(c)

(a) No preheat. Areas to be hard faced were heated to sweating temperature with the torch used to deposit the hard facing alloy. (b) Includes machining time. (c) For torch, regulators, hoses, tips, goggles, table and blocks.

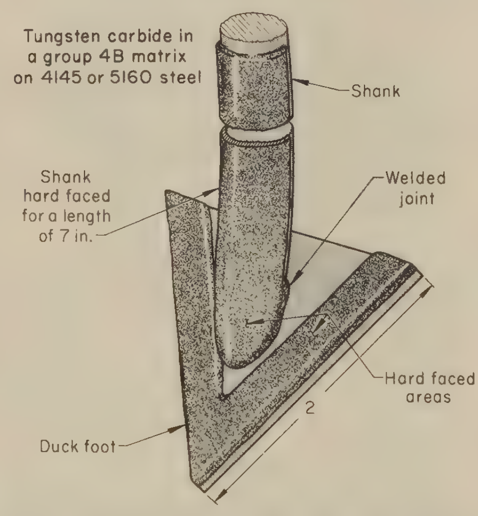
Fig. 8. One section of an eight-section blanking die that was repaired by hard facing, using powder-spray oxyacetylene welding (Example 538)



Weld type	Hard facing; joining
Thickness of hard facing	0.020 to 0.030 in.
Hard facing alloy	Group 4B powder(a)
Welding position	Flat
Gas pressure:	
Acetylene	9 psig
Oxygen	22 psig
Preheat	600 F
Postheat	None
Production rate	One piece every 3 min(b)
Cost per piece (labor and material)	$1.50
Equipment cost, per welder	$450(c)

(a) Tungsten carbide was usually added (40 to 50%). (b) Includes welding duck foot to shank. (c) Approximate cost; includes torch, regulators, hoses and exhausts.

Fig. 9. Tillage tool used for introducing liquid ammonia into the soil. The operations included hard facing of the shank, and hard facing of the duck foot and welding it to the shank in a single operation. (Example 539)

Example 538. Powder-Spraying Method for Hard Facing Edges of Blanking Dies (Fig. 8)

Chipped cutting edges (Fig. 8) of dies used for blanking automotive parts from 11-gage (0.1196-in.-thick) low-carbon steel sheet were regularly repaired using a method based on feeding a powdered mixture of a nickel-base hard facing alloy and fine-mesh tungsten carbide through an oxyacetylene torch. Sometimes, for filling large chipped areas, additional hard facing alloy was hand fed from rod. The mixer part of the torch had an opening into which was screwed a moistureproof, bellows-type can containing the powdered alloy. A lever extending to the torch handle was depressed to start powder flow into the stream of oxyacetylene gas.

The work-metal surfaces were cleaned with a power-driven wire brush. The oxyacetylene torch was then adjusted for a neutral flame. The flame was played over the area to be welded until the surface reached a dull-red heat, and then it was concentrated momentarily on the starting area (keeping the torch in constant motion). The powder-dispensing lever was slowly depressed, and powder was distributed and fused over the weld area, to a height slightly above the die surfaces. The die section was cooled in air.

The weld deposit was ground flush with the die surfaces, and the die was returned to service without postheating. The hardness of the deposit ranged from Rockwell C 57 to 64.

Edges repaired by this procedure were quite satisfactory; they generally remained intact until the sections were ground below the repairs in resharpening.

Agricultural tools that are often hard faced include plowshares, disks, sweeps, and subsoil points of various types. The life of most of these tools can be prolonged by hard facing, but the cost of hard facing is high and cannot always be justified. For operation in some soils, such as those in Oklahoma and southern Kansas, tillage

tools must be hard faced for acceptable life. The extra cost of hard facing cannot be justified for tillage tools used in the less abrasive soils of the corn belt.

The example that follows describes an application where hard facing, using the powder-spraying method, increased the life of tillage tools by six to eight times.

Example 539. Hard Facing a Shank and a Duck Foot and Simultaneously Welding the Duck Foot to the Shank (Fig. 9)

To increase the life of the tillage tool shown in Fig. 9, which was used to introduce liquid ammonia fertilizer into the soil at a depth sufficient to avoid excessive evaporation, hard facing was applied to the leading surface of the shank and on the edges of the duck foot. The duck foot was welded to the shank in the same operation.

The components, of either 4145 steel or 5160 steel, were preheated to 600 F. First, the shank, which was the thicker of the two components, was heated with a powder-spraying-type torch to the hard facing temperature (judged by the welder). Then, the leading surface of the shank was hard faced for a distance of about 7 in. by spraying on a nickel-base alloy powder that contained 40 to 50% of tungsten carbide particles. The duck foot was heated and its edges were hard faced in a similar manner, and the foot was welded to the shank.

The hard faced tools lasted six to eight times longer than tools that were not hard faced, under the same service conditions. Other hard facing conditions are given in the table that accompanies Fig. 9.

Hard Facing of Cast Iron. Because of their relatively poor weldability, gray, malleable and ductile cast irons are hard faced less frequently than are steels, but the example that follows describes how a wear problem involving a ductile iron casting was solved by hard facing with a sprayed-on powder.

Example 540. Ductile Iron Castings Hard Faced on High-Wear Areas by the Powder-Spraying Method (Fig. 10)

Stone and sand thrown by the track of a crawler tractor caused severe wear on a 10-sq-in. area of a ductile iron transmission housing (see Fig. 10). This area was sometimes worn through after a few months of operation.

Three different methods of protecting the high-wear area were tried. The first method was to cover the vulnerable area with a hardened steel plate secured by bolting, but this was unsatisfactory because the bolt heads were mutilated beyond use in a short time. A second approach was to hard face the surface by arc welding. Several different hard facing alloys were tried, but application of the hard facing alloy was too slow, and concern over the possible propagation of cracks into the base metal from weld checks was a deterrent. The third approach was to spray the vulnerable area with a powdered mixture of nickel-base alloy and tungsten carbide through an oxyacetylene torch. This method was simple and rapid.

Equipment cost was moderate. Although the alloy and carbide powders were expensive, only 1½ oz was needed to deposit a typical overlay ranging from 0.010 to 0.030 in. thick. This hard faced layer did not separate from the base metal when tested by striking with a ball-peen hammer, and proved to be satisfactory in service. Micrographs showed no adverse effects on the ductile iron microstructure at the interface between the hard facing and the base metal. This fact was attributed to the relatively low peak temperature involved.

Before welding, the area to be hard faced was marked off, and surface oxide was removed by grinding. The general area was then locally preheated, using the oxyacetylene torch. A light coating of metal powder was deposited over the area and was heated until the surface was uniformly wetted. Additional metal powder was then applied to build up the hard facing layer to an average thickness of about 0.020 in.

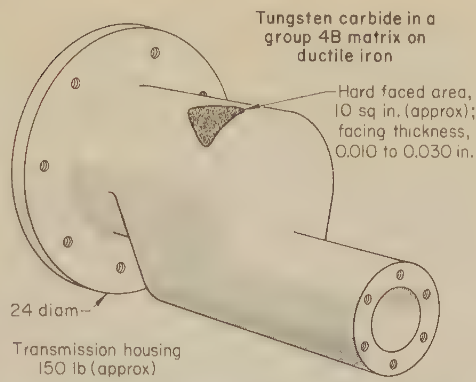


Fig. 10. Drop-housing portion of the transmission on a crawler tractor, showing area subjected to severe wear from stones and sand cast off by the track (Example 540)

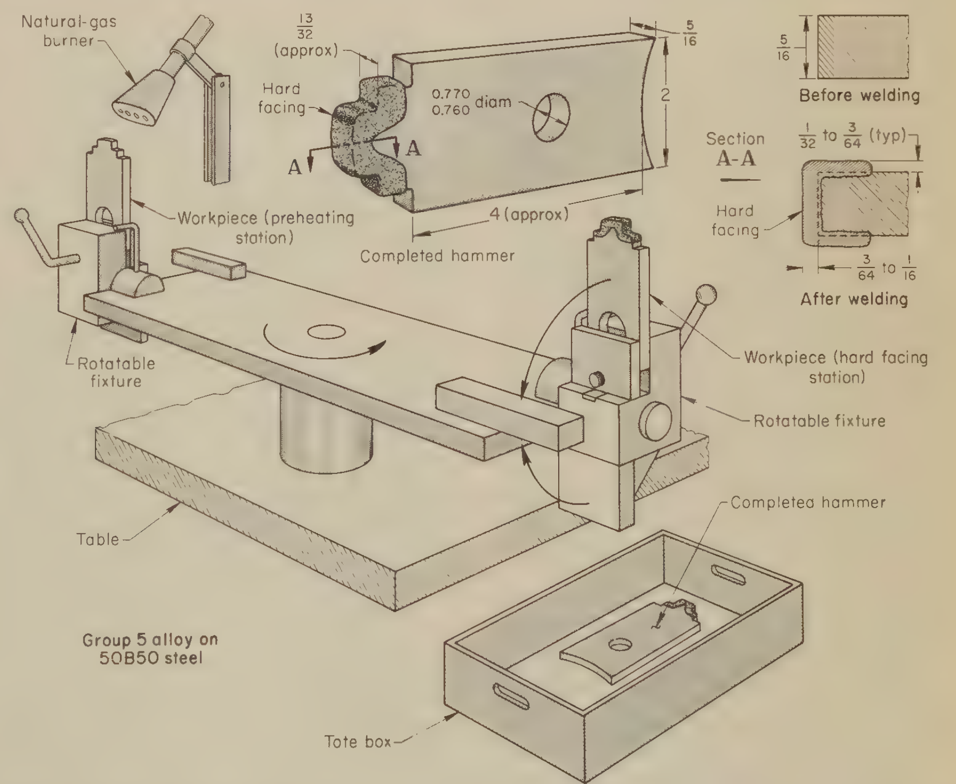
Mechanized Handling of Workpieces

For repetitive work, various types of mechanized handling and workholding devices are used. The two examples in this section describe and illustrate relatively simple mechanisms used for production hard facing.

Feed-Mill Hammers. In new equipment, feed-mill hammers are supplied in the heat treated condition or hard faced. Because of the severely abrasive conditions of service, a hard faced hammer can have a life eight times as long as that of a heat treated hammer, and often the user will hard face hammers before they are put in service, if they were purchased unfaced in the heat treated condition. A procedure for production hard facing of feed-mill hammers is described in the example that follows.

Example 541. Use of Rotating and Swiveling Fixtures for Production Hard Facing of Hammers (Fig. 11)

The feed-mill hammer shown in Fig. 11, made from annealed 50B50 steel, was hard faced with a tungsten carbide composite (group 5 alloy). All surfaces of the hammer were milled before hard facing, to ensure a clean, scale-free surface, and the machined hammer was straightened. It was then hard faced by means of the two-station setup shown in Fig. 11. This setup enabled the operator to preheat one hammer while he was hard facing another. A simple swivel arrangement brought the preheated hammer to the hard facing station, where the fixture was rotated for flat-position welding. After hard facing, the hammer was released from the fixture and



Welding Conditions

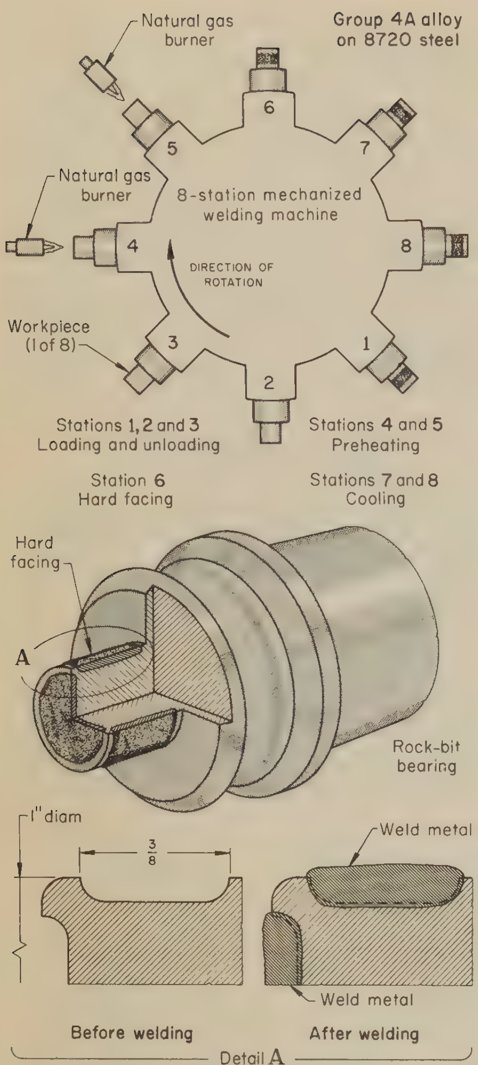
Weld type	Hard facing
Thickness of hard facing	1/32 to 1/16 in.
Hard facing alloy	Group 5(a)
Gas flow:	
Acetylene	44 to 56 cfh
Oxygen	43 to 54 cfh
Preheat	1000 to 1200 F
Postweld heat treatment	Furnace harden and temper to Rockwell C 50 to 56
Production rate	One hammer every 1.48 minutes; 2.96 minutes total preheating and hard facing time

Cost Items

Welding torch, preheat burner, regulators, fixtures, piping and accessories	$400.00
Hard facing alloy, per pound	$3.25
Hard facing alloy and gases, per hammer	$0.062

(a) Tube metal rod (1/8 in. in diameter by 14 in. long) contained 3.7 to 4% carbon and a minimum of 60% tungsten carbide; amount of rod used per hammer was about 0.0075 lb.

Fig. 11. Feed-mill hammer, and setup for preheating and hard facing it (Example 541)



Weld type	Hard facing
Thickness of hard facing	$\frac{3}{32}$ to $\frac{1}{8}$ in.

Oxygen	12 cfh
Preheat	1000 to 1200 F
Finishing operation	Grinding

(a) Cobalt-base alloy with 24 to 28 Cr, 12 to 15 W, 10 Fe max, 3.0 to 3.5 C, 0.5 to 1.0 Si

Fig. 12. (Upper) Plan view of an eight-station rotary holding device for mechanized hard facing. (Lower) Rotary rock-bit bearing and areas to be hard faced, before and after welding. (Example 542)

dropped into a tote box. The empty fixture was then loaded with another hammer and moved to the preheating station.

The hard facing operation was completed in 1.48 min, and therefore the distance between the preheating torch and a hammer had to be such that a hammer would be preheated to the correct temperature in the same length of time.

Other hard facing details are given in the table that accompanies Fig. 11.

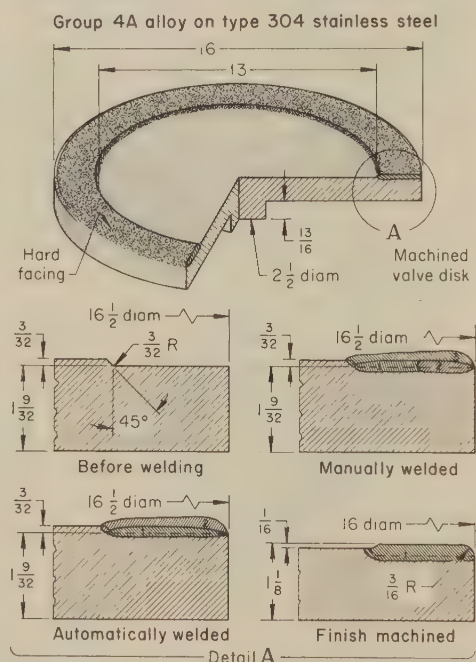
Rotary rock-bit components are subjected to extremely severe service conditions. They often operate several thousand feet underground, and because much time is required to change tools, every effort is made to prolong their life. Hard facing the wearing surfaces with a cobalt-base alloy (such as one of the group 4A alloys) has proved effective in prolonging their life. A manual procedure for this operation is described in Example 532. A mechanized procedure is described in the example that follows.

Example 542. Hard Facing Rotary Rock-Bit Bearings in a Mechanized Setup (Fig. 12)

Rotary rock-bit bearings, such as the one shown in Fig. 12, were hard faced in production quantities by means of the equipment shown schematically in Fig. 12. Mechanization was justified when annual production exceeded 50,000 bearings.

The mechanized welding machine consisted of a rotating table on which eight fixtures for holding and rotating bearings were mounted. Around the table were eight stations for loading, preheating, hard facing, cooling and unloading bearings.

Each bearing was machined to the typical dimensions given in Fig. 12 (Before welding) and thoroughly cleaned. To begin the hard facing sequence, four fixtures were loaded with bearings. The first bearing was preheated to 1000 to 1200 F at stations 4 and 5 by natural-gas burners. It was then moved into position in front of the operator at the hard facing station. The torch used for hard facing was manipulated manually. When hard facing was completed, the table was rotated to the next position, thereby placing another preheated bearing in position to be hard faced, and advancing the hard faced bearing to a cooling station. After the first hard faced bearing had moved through cooling stations 7 and 8, it was removed from the turntable and replaced by a bearing to be preheated and hard faced.



Weld type	Hard facing
Thickness of hard facing	$\frac{5}{32}$ in. min
Hard facing alloy	$\frac{5}{16}$-in.-diam group 4A(a)
Welding position	Flat
Gas pressure:

Sweating	0.040-in.-diam orifice, $\frac{13}{16}$ in. long
Hard facing	0.0465-in.-diam orifice, $\frac{15}{16}$ in. long
Preheat	800 to 1000 F
Cooling method	Cool slowly in powdered asbestos
Inspection	Liquid penetrant(b)

(a) Cobalt-base alloy with 28.5 Cr, 4.5 W, 3.0 Ni max, 1.10 C. (b) After final machining. No linear indications, and no rounded indications more than $\frac{3}{32}$ in. in diameter, were permitted.

Fig. 13. Gate-valve disk that was hard faced in an automatic setup (Example 543)

Additional details of the hard facing step of the mechanized procedure are given in the table that accompanies Fig. 12.

Automatic Hard Facing

Hard facing by oxyacetylene welding can be completely automatic, which means that the workpieces are mechanically fed and rotated under a hard facing torch that is mechanically held and manipulated. Configuration of the surface and quantity of identical parts to be hard faced are the principal factors that determine whether it is practical to automate the process. In some applications, the configuration of the surface to be hard faced is so complex that mechanical manipulation of the torch is not practical, regardless of production quantities. An application in which automatic hard facing proved advantageous is described in the example that follows.

Example 543. Gate-Valve Disks Hard Faced by Automatic Welding (Fig. 13)

When type 304 stainless steel gate-valve disks were automatically hard faced with a group 4A alloy, the time required for welding was reduced from 100 to 40 minutes, and the number of layers, from three to two, as compared with manual welding. However, the automatic method could be used only when a lower hardness and poorer quality could be tolerated. The manual technique used was essentially the same as described for the valve seat in Example 531.

Using the automatic method, the workpiece was rotated, and hard facing was done in the flat position. Four torches were used: two for preheating, one for bringing the workpiece surface to the sweating temperature, and one for hard facing. For preheating, the flame was adjusted to neutral; for bringing the workpiece to the sweating temperature, a reducing flame was used (2× to 3× feather); and for melting the hard facing rod, the flame was again neutral. The two preheating torches provided supplemental heat, and were separately supported on a stand. The torches used for sweating and hard facing were oscillated to ensure a uniform deposit.

The hard facing alloy (in rod form) was fed by gravity. The rods were positioned vertically by guides attached to the oscillator, but were allowed to rest on the work surface.

The workpiece was prepared by machining, cleaning with acetone, preheating in a furnace at 800 to 1000 F, and brushing with a wire brush.

The hard facing deposit was built up in two layers. The first layer was kept as thin as possible and puddling was minimized to prevent excessive dilution with the base metal. Following the automatic welding, the deposit was drawn out with a hand-held torch and filler metal was added as required to avoid shrinkage at the termination of the weld and to ensure cleanup in the final machining operation. After hard facing, the disks were buried in powdered asbestos and permitted to cool slowly.

Quality was checked by liquid-penetrant inspection. No linear indications, and no rounded indications more than $\frac{3}{32}$ in. in diameter, were allowed in accepted welds.

Qualification of the procedure required that one sample piece, at least 8 in. in diameter by 4 in. thick, be hard faced, and four sections be cut from it for liquid penetrant inspection, hardness testing (Rockwell C 38 min), and microscopic examination of cross sections at a magnification of 40. Each section was required to be free of cracks, incomplete fusion, linear defects, and porosity greater than 0.015 in. in diameter.

Additional hard facing details are given in the table that accompanies Fig. 13.

BRAZING

CONTENTS

Furnace Brazing of Steel

*By the ASM Committee on Brazing of Steel**

FURNACE BRAZING is a mass-production process for joining the components of small assemblies by a metallurgical bond, using a nonferrous filler metal as the bonding material and a furnace as the heat source. Furnace brazing is feasible only if the filler metal can be preplaced on the joint before brazing and retained in position during brazing. This article describes the application of furnace brazing to the joining of carbon and low-alloy steels, usually with a copper filler metal and occasionally with a silver alloy filler metal. Furnace brazing of other metals is dealt with in individual articles in this volume.

Furnace brazing requires the use of a suitable atmosphere to protect the steel assemblies against oxidation, or oxidation and decarburization, during brazing and during cooling, which is accomplished in chambers adjacent to the brazing furnace. The proper brazing atmosphere also makes possible the proper wetting of the joint surfaces by the molten copper filler metal, usually without use of a brazing flux (Example 557 describes an exception).

Although filler metals other than copper can be used in furnace brazing carbon and low-alloy steels, copper is generally preferred because of its low cost and the high strength of the joints produced. The high brazing temperature necessary when copper filler metals are used (2000 to 2100 F) is also advantageous when steel assemblies are to be heat treated after brazing.

Applicability

In general, the steel assemblies that are brazed most efficiently and economically are small and weigh less than 5 lb. Much larger assemblies can be brazed in specially built furnaces; the size of assemblies is limited by the heat required to bring them to the brazing temperature. Most steel assemblies are brazed at 2000 to 2100 F. This temperature, which is considerably higher than those employed in the heat treatment of steel, imposes limitations on furnace design and operation, including the maximum feasible size of the heating chamber, the degree of tightness and temperature uniformity that can be maintained, the time required to heat the workpieces to the brazing temperature, and the weight of loads that can be supported at 2000 F without sagging of furnace fixtures.

Among the steel components that are commonly furnace brazed are machined parts, light stampings, deep drawn sheet-metal parts, small forgings, and some castings. Usually, components are designed to be "self-jigging" — that is, capable of being assembled for brazing without the use of fixtures. Fixtures are sometimes required, but are avoided whenever possible; they add weight and change in dimensions after repeated exposure to elevated temperature. Among the many methods used to ensure adequate assembly for brazing are staking, expanding, spinning, swaging, knurling, crimping, press fitting, and tack welding. These, and other methods, are discussed in detail in the section on Assembly for Brazing, pages 603 to 607.

Advantages. The principal advantage of furnace brazing over other brazing processes is that it permits the use of a variety of prepared protective atmospheres, notably the rich exothermic-base, the endothermic-base, and some nitrogen-base atmospheres. These atmospheres are among the least expensive; they can be generated in the plant in large volume; they provide excellent protection against oxidation; and they can be prepared with any carbon potential in the range of about 0.2% to more than 1.0% C, depending on the atmosphere. This range of carbon potential is sufficient to accommodate all carbon and low-alloy steels, including those carburized before brazing. By selecting an atmosphere with a carbon potential that matches the carbon content of the work metal, brazing can be accomplished without carburizing or decarburizing the work metal.

Because the protective atmospheres used for furnace brazing are suffi-

Some of the examples presented in this article were contributed by members of other Metals Handbook welding and brazing committees.

ciently reducing to iron oxide, they usually eliminate the need for fluxes when brazing carbon steel with copper filler metal. These atmospheres can reduce light oxide films present on the surfaces of workpieces at the time of entry into the furnace, and they can prevent any further oxidation of the surfaces during the brazing cycle. An oxide-free surface normally promotes ready wetting of the workpiece by the molten filler metal. However, some low-alloy steels that contain a total of more than 2 or 3% of chromium, manganese, aluminum and silicon form more stable surface oxides, and they require highly reducing atmospheres (such as dry hydrogen or dissociated ammonia), a flux, or nickel plating to obtain adequate wetting action.

Another major advantage of furnace brazing is its ability to process large quantities of assemblies at low unit cost on either a batch or continuous basis. Furnace brazing is most efficient and economical when used in mass production, but it is sufficiently flexible to handle occasional small loads and low-production items, although at a higher unit cost.

Furnace brazing sometimes replaces another brazing process to increase the production rate. For instance, masonry drills of the type shown in Fig. 1 were initially assembled by induction brazing the sintered carbide tip to the low-alloy steel body, using a silver alloy filler metal. A slot was milled in the cutting end of the drill body to receive the sintered carbide tip with a light press fit. When it became necessary to produce these drills in larger quantities, furnace brazing was selected to replace induction brazing. The press fit used for induction brazing was found to be adequate to hold the drill body and carbide tip in position during furnace brazing, but the filler metal was changed to a copper paste slurry into which the tips were dipped before assembly. The drills were carried through the brazing furnace on a mesh-belt conveyor at a speed adjusted to give maximum penetration of the filler metal. Brazing was at 2030 to 2050 F, and production rate was 1000 to 1100 3⁄16-in.-diam drills per hour and 500 to 600 5⁄8-in.-diam drills per hour.

Furnace brazing can provide close temperature control and uniformity at all stages of the brazing cycle, including cooling. It can provide atmospheric protection during both heating and cooling. It can provide a different protective atmosphere in different chambers or compartments of the furnace, although this is rarely done. Also, furnaces of special design make it possible to braze in a controlled vacuum, although this is seldom done in brazing carbon and low-alloy steels.

Furnace brazing provides a uniform distribution of heat in the mating parts of the joint at the brazing temperature. However, if the difference in sectional thickness of the parts to be brazed is great, it is sometimes necessary to preheat them to just below the melting point of the filler metal, soak them until the heat is equalized, and then increase the temperature to the brazing range. If joint design and fit are satisfactory, and the correct amount and form of filler metal is provided, brazed joints are uniformly strong and sound. Several joints on the same assembly can be brazed in a single operation. With proper atmospheric protection, the brazed assemblies that leave the furnace cooling chamber (at about 300 F) are clean and bright, requiring no cleaning.

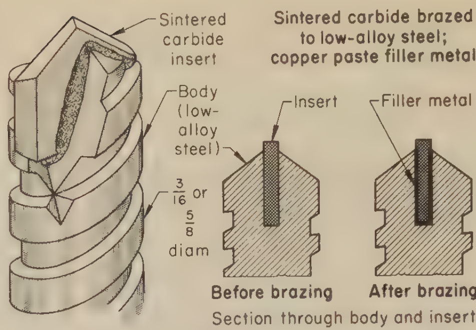

Fig. 1. Masonry drill with carbide tip that was furnace brazed to drill body to meet high production requirements

Limitations. Most of the limitations of furnace brazing are directly related to the high temperatures required to braze with copper filler metal. These temperatures exceed the average brazing temperature required to braze with silver alloy filler metals by 500 F or more. They are high enough to cause grain coarsening in medium-carbon, high-carbon and low-alloy steels; however, grain refinement can be obtained by subsequent heat treatment. The high brazing temperatures adversely affect the life of furnace components, especially those components that are exposed to the maximum temperature, such as furnace linings, electrical heating elements, muffles, rails, trays and conveyor belts.

The initial cost of a furnace and atmosphere generator is high, compared with that of most other types of brazing equipment. For this reason, the purchase of furnace brazing equipment cannot be justified for a new project if production quantities are low, and another brazing method may have to be considered. However, if a brazing furnace is already available, a few assemblies can be brazed economically.

Generator-prepared atmospheres may contain toxic compounds. Those that have a total of 5% or more of combustible gases (H_2, CO and CH_4) constitute a potential fire and explosion hazard. Safe operating practice and preventive maintenance of furnaces, generators and venting systems are mandatory (see the Appendix on Safe Operation of Brazing Furnaces, which begins on page 614).

Most of the disadvantages related to the life of furnace components have been lessened by improvements in furnace design and materials. For example, the average life of a refractory brick lining in a modern copper brazing furnace is about five years. The life of a high-temperature alloy muffle in a gas-fired furnace is about one year.

Sequence of Operations

Furnace brazing entails four processing operations: cleaning, assembling and fixturing, brazing, and cooling.

Cleaning is generally limited to the removal of oils used in machining operations. The preferred cleaning methods are alkaline cleaning, solvent cleaning, and vapor degreasing. When alkaline cleaning is used, it is important that all alkaline compounds be removed from workpieces before they enter the brazing furnace. Pigmented drawing compounds containing lead are generally removed by mechanical cleaning methods, such as dry grit blasting or wet blasting with an abrasive slurry. If they are not completely removed, drawing compounds containing lead are extremely detrimental to the quality of the brazed joint and to the life of furnace components.

Assembling and Fixturing. Components to be furnace brazed are generally designed for assembling by press fitting, expanding, swaging, or other means that eliminate the need for fixtures. However, fixtures are occasionally required for holding parts in proper relationship or for positioning an assembly in the brazing furnace so that the molten filler metal flows in the required direction.

The cleaned components are assembled with filler metal applied within or adjacent to the joints to be brazed. Assemblies are then loaded onto trays for batch-type or roller-hearth continuous furnace brazing or are transferred directly to the conveyor for mesh-belt conveyorized furnace brazing.

Brazing. The assemblies are moved into the brazing chamber of the furnace, where they are heated under a suitable protective atmosphere. When the assembly reaches a temperature higher than the melting point of the filler metal, the filler metal wets and flows over the steel surfaces and is drawn into the joints by capillary action. In making the bond, the filler metal forms a solid solution with, but does not melt, the steel surface. Heating time for furnace brazing most steel assemblies is from 10 to 15 min.

Cooling. The assemblies are moved to the cooling chamber of the furnace, where they are cooled under a protective atmosphere (usually the same atmosphere as was used in the brazing chamber). They remain in the cooling chamber until they have cooled enough so that they will not discolor when exposed to air — usually to about 300 F.

Summary of Operating Conditions. Table 1 is a summary of the conditions for furnace brazing that were employed in 29 of the 30 examples of commercial practice presented in this article. Table 1 identifies the assembly by name, lists the steels being brazed, the method of assembly, the filler metal, the type of furnace used, the protective atmosphere, the furnace temperature and heating time, and the production rate.

Brazing Furnaces

The furnaces most often used in the furnace brazing of steel assemblies are box furnaces, mesh-belt conveyor furnaces, and roller-hearth conveyor furnaces. All three types can be gas fired or heated by electricity, but for copper brazing at 2050 F, the roller-hearth type is usually electric. Gas-fired braz-

Table 1. Summary of Furnace Brazing Conditions Employed in Applications Described in Examples in This Article

Example number	Name of assembly	Base metal	Method of assembly	Filler metal	Type of furnace	Protective atmosphere	Furnace temperature, F	Heating time, minutes	Assemblies brazed per hour

(v) For each of two furnaces used.

ing furnaces require the presence of a heat-resisting alloy muffle in the heating chamber to prevent the products of combustion from contaminating the protective atmosphere. Electric furnaces are usually operated without a muffle, and thus avoid the baffling of heat and the sometimes reduced production that may be encountered with a muffle, as well as the costs of maintaining and replacing the muffle. All furnaces must be sufficiently gastight to contain a protective atmosphere.

Furnace Ratings. The capacity of a brazing furnace is generally expressed in terms of gross weight of work load processed per hour. Trays, fixtures and conveyor belts are included in gross weight and are estimated to be about one-third of the total work load. Thus, a furnace with a gross-weight capacity of 150 lb per hour can be expected to process about 100 lb of assemblies per hour. Ratings are based on copper brazing of steel assemblies at a maximum temperature of 2100 F.

Box Furnaces. A box-type brazing furnace that is heated by electricity is shown schematically in Fig. 2. It consists of a heating chamber and a water-jacketed cooling chamber that is at least three times as long as the working length of the heating chamber. In standard models, the working length of the heating chamber ranges from 26 to 36 in.; the length of the cooling chamber ranges from 84 to 114 in. Door openings are 8-by-8 in. to 18-by-18 in. The brazing atmosphere, which is supplied by a generator (not shown in Fig. 2), is maintained within both the heating and cooling chambers. Throat baffle doors, which are normally closed, serve to increase effective heating length and to reduce end losses. Sliding doors at the entrance and exit of the furnace, also normally closed, help to maintain the protective atmosphere inside the furnace at high purity and to reduce the loss of atmosphere. The end doors are equipped with automatic gas-flame curtains.

The refractory-brick walls and roof of the heating chamber are backed up with thermal insulation. The load-carrying hearth plates are made of a heat-resisting alloy, silicon carbide, or alumina. Side rails (not shown in Fig. 2) serve to guide trays and to protect sidewall heating elements. The heating elements under the hearth plates and on the sidewall and roof are spaced to ensure temperature uniformity and are regulated by thermocouples.

The brazing atmosphere is fed to both heating and cooling chambers through inlets located outside the exit baffle door. Gas flow is manually set and is measured by a flowmeter. An inlet for purging gas is located inside the heating chamber to provide gas for "burnout". A protective-atmosphere venting system is not usually required with box-type furnaces, because the entrance and exit doors are never opened at the same time, thus avoiding contamination of the atmosphere by a through draft of air.

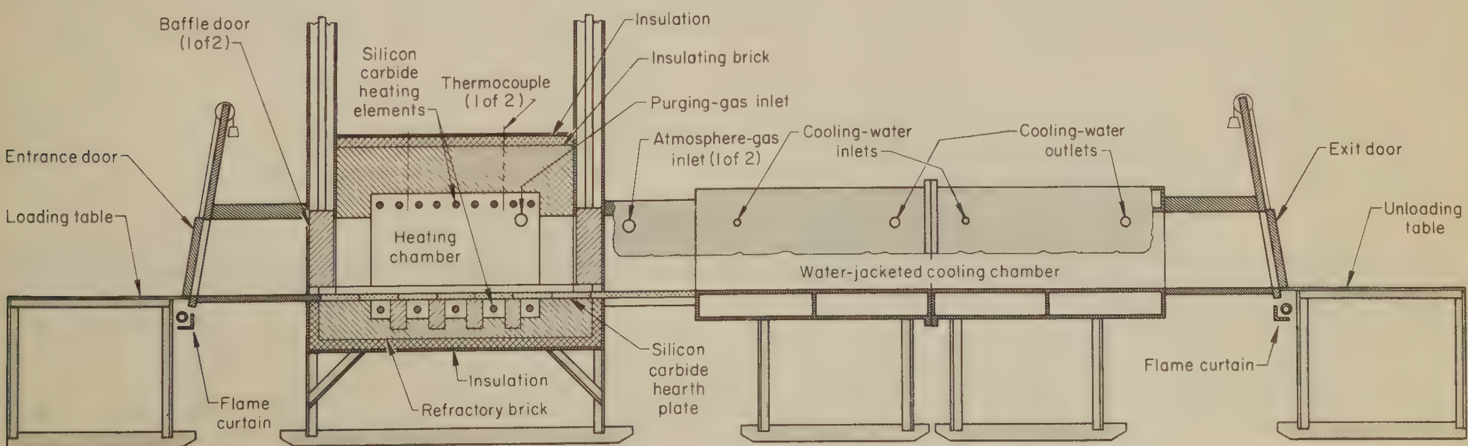

Fig. 2. Box-type brazing furnace with a water-jacketed cooling chamber

The cooling chamber is constructed in one or more segments, which are joined together and to the heating chamber by welding or by bolting with gaskets at interconnecting flanges, to provide a gastight seal. Each segment is equipped with its own water-cooling system, thereby providing maximum control of cooling from zone to zone. The temperature of the cooling water is thermostatically controlled, to minimize water consumption and to avoid condensation in liners during furnace idling. (When work is resumed, condensed moisture could turn to steam and cause oxidation of steel parts.)

Typically, such a furnace will accommodate four trays at a time: one in the heating chamber and three in the cooling chamber. As soon as the tray in the heating chamber reaches brazing temperature, the operator pulls the end tray out of the cooling chamber and pulls the other two trays closer to the end. He then pushes the hot tray of brazed assemblies into the empty space in the cooling chamber, and pushes a new tray of unbrazed assemblies into the heating chamber.

Mesh-belt conveyor furnaces offer the advantages of continuous operation at high capacity, and accurate, automatic cycle timing in both the heating and cooling chambers. An electrically heated, mesh-belt conveyor furnace, incorporating several special features, is shown in Fig. 3. Standard models of this furnace are made with mesh-belt widths ranging from 6 to 36 in. and hearth areas of up to 33 sq ft. Large-diameter (24 in. or more) drive and idler pulleys and flat return plates prevent sharp or reverse bends in the belt, thus extending belt life. The drive and pinch rolls are rubber faced. The belt take-up is a catenary loop at the driving end of the conveyor, which allows up to 4 ft of belt stretch before the belt has to be shortened. This take-up mechanism produces minimum tension on the belt, and allows the belt to contract automatically when the furnace is shut down. The belt is driven by an electric motor equipped with a variable-speed control and located under the loading area. Several wrought stainless steels, including type 314, are satisfactory belting materials.

The construction of the heating chamber, including the brickwork, is similar to that of a box furnace. Refractory-lined baffle doors, such as those shown on the box furnace of Fig. 2, can also be installed. These are manually adjusted to the precise height of the work load or to close the throats completely during standby. The height of the end doors can also be adjusted to reduce the consumption of protective atmosphere and to aid in directing atmosphere flow. The exit door is equipped with a flame curtain. As with the box furnace, brazing atmosphere is fed to both the heating and cooling chambers through inlets located outside the heating-chamber exit baffle. The control of brazing-atmosphere flow is described in the subsequent section on Venting for Mesh-Belt Conveyor Furnaces. The cooling chamber is similar to that of a box furnace.

Heating chambers of mesh-belt conveyor furnaces commonly range in length from about 2 to 12 ft; cooling chambers are at least three times as long. Representative ratings for copper brazing of steel assemblies are 120 to 1200 lb of assemblies per hour.

Roller-hearth conveyor furnaces are continuous furnaces in which the conveyor consists of driven rolls made of a heat-resisting alloy. The ends of the rolls extend through the sidewalls of the heating and cooling chambers, where they are held in suitable bearings and are rotated by sprockets and an endless chain controlled by a variable-speed driving mechanism.

Roller-hearth furnaces are generally used for high production, particularly when loading density or height of assemblies is considerably above average. Some furnaces have door openings up to 30 in. high, requiring the use of purging chambers preceding the heating chambers to prevent contamination of the brazing atmosphere.

Assemblies to be brazed can be loaded directly on the roll table, if they are long enough, but more commonly they are loaded on flexible trays made of a wrought or cast heat-resisting alloy. Trays range from 30 to 36 in. long and from 18 to 30 in. wide.

There is virtually no limit to the length of the heating and cooling chambers in roller-hearth furnaces. Typical production rates range from 350 to 2000 lb of brazed assemblies per hour. Extra-long furnaces have produced up to 3700 lb of assemblies per hour.

Furnace Idling. When a copper brazing furnace is to be idle for only one shift, the temperature is reduced to about 1800 F and the flow of brazing atmosphere is maintained. For idling over a longer period, a temperature of 1400 to 1600 F is satisfactory. When the furnace contains a flammable atmosphere, it may be purged, either by the burnout method or by the introduction of nonflammable gas. At the end of the idling period, the purging operation is reversed and the flammable atmosphere is reintroduced into the furnace. Methods of purging, including the burnout method, are discussed in the Appendix on Safe Operation of Brazing Furnaces, beginning on page 614.

Venting for Mesh-Belt Conveyor Furnaces

Proper venting of mesh-belt brazing furnaces is of prime importance in avoiding discoloration or decarburization of assemblies because of contamination from infiltrating air, air or moisture contained in assemblies, gas flame curtains, and volatilized oil from unclean components, and in preventing the contaminants from drifting in the wrong direction through the heating and cooling chambers. A venting system of poor design can counteract the beneficial effects of the brazing atmosphere. In general, the brazing atmosphere should flow toward the ends of the furnace. With this flow pattern, the atmosphere flows *counter* to the work in the heating chamber, sweeping air and contaminants from the entrance, and it flows *with* the work in the cooling chamber, providing protection up to the point of exit.

Drafts. The direction of room drafts often corresponds to the direction of the wind outside, particularly if doors and windows are open. Sometimes, large baffles are installed across the ends of furnaces to block or deflect room drafts. Exhaust hoods with stacks are mounted at the furnace ends over the door openings, to reduce drafts further and to carry away the hot products of combustion. Also, the input flow of brazing atmosphere at various points in the furnace can be adjusted to meet the demands of the moment. Because all of these techniques for draft control are subject to failure, properly designed exhaust hoods and ductwork systems are needed.

Poor Design for Venting. Typical of poor venting design is the system shown in Fig. 4(a). Stacks from exhaust hoods at the entrance and exit ends of the furnace go directly out through the plant roof, and have no

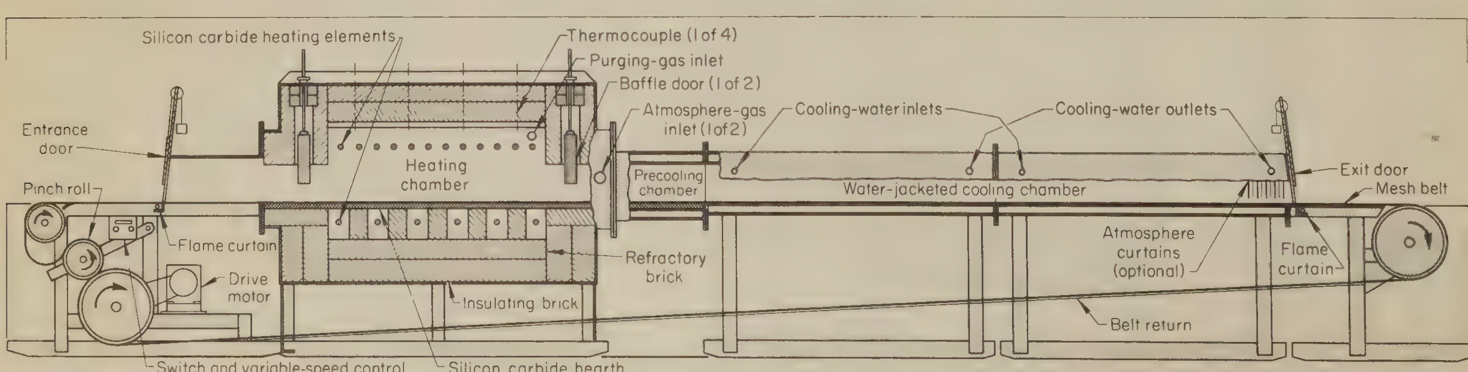

Fig. 3. Mesh-belt conveyor brazing furnace with a water-jacketed cooling chamber

dampers for adjustment of draft. Because winds blowing over the top of one stack do not necessarily travel with the same velocity over the top of the other stack, there is a difference in the amount of suction in the two stacks. Also, the differential velocities can reverse from hour to hour, and this can affect the direction or velocity of flow of brazing atmosphere through the furnace. Because the stacks are connected directly to the hoods, downdrafts can blow air into the heating and cooling chambers, contaminating the brazing atmosphere and disrupting temperature uniformity. In addition, the hoods are located over the tops of door openings only, leaving the sides and bottoms unprotected, and they are therefore ineffective in blocking room drafts, although this is their intended function.

Effective Venting. A successful venting system is shown in Fig. 4(b). With this system, the exhaust hoods feed into open collectors with dampers, not directly into stacks. The collectors draw in room air along with the hot products of combustion, which helps to cool the stacks and to minimize downdrafts. Ducts from the collectors lead to a single stack through the roof, which, with or without an exhaust fan and depending on the room height and the amount of natural draft, prevents variations in stack draft. The dampers permit adjustment of stack draft to control the direction of flow of brazing atmosphere through the entire furnace, ensuring that this flow is outward toward the end doors. This provides maximum protection and minimum contamination in the heating and cooling chambers.

Adjustable end doors are another feature that contributes to successful operation of the venting system shown in Fig. 4(b). The end doors are lowered so that they are as close to the tops of the workpieces as possible to reduce air infiltration and to minimize atmosphere consumption. Raising the door at one end of the furnace slightly higher than that at the other end creates a draft or chimney action, which also counterbalances room drafts.

As shown in Fig. 4(b), the door at the entrance end (left) is set higher than that at the discharge end (right), and the damper in the collector at left is farther open than that at the right. This encourages maximum counterflow of the brazing atmosphere, which enters the furnace at the hot end of the cooling chamber. The atmosphere is preheated by the outgoing hot workpieces and, after passing through the heating chamber, forces air and other contaminants out through the entrance door. If a room draft is flowing mildly in this same counterflow direction, air can infiltrate the cooling chamber with adverse effects. To counteract this condition, the damper and end door at the exit end are opened and those at the entrance end are partially closed. This counterbalances the room draft and still provides a rate of flow of brazing atmosphere out of the entrance end. Unless the venting system is subjected to extremely strong room drafts, the design in Fig. 4(b) affords complete control of the flow of atmosphere through the furnace in either direction.

Protective Furnace Atmospheres

The gas atmospheres used in furnace brazing serve primarily to protect the steel assemblies from oxidation or scaling and to assist the flow of filler metal by promoting wetting of steel surfaces. Both functions require a gas atmosphere that is reducing. When required, the atmosphere may also serve to maintain the carbon content of the steel, by preventing carburization or decarburization at elevated temperatures. To satisfy all requirements, the atmosphere must provide complete protection to assemblies in both the heating and the cooling chambers of the brazing furnace.

Rich Exothermic-Base Atmosphere. In theory, almost any reducing atmosphere can be used in furnace brazing of low-carbon steel with a copper filler metal. In practice, a rich exothermic atmosphere is usually selected, because it is the least expensive of the generated atmospheres, is adequately reducing, has relatively low sooting potential compared with drier atmospheres containing more carbon monoxide, and requires a minimum of generator maintenance.

The content of reducing gases in a rich exothermic atmosphere (12.5 to 15% H_2 and about 11% CO) usually is sufficient to promote good wetting and to maintain bright surfaces on steel assemblies. When hydrogen is low and moisture is high, refrigeration of the gas to reduce its dew point is required to ensure bright surfaces.

The carbon potential of the atmosphere is normally low (about 0.10% C), but it can be increased to about 0.40% C by decreasing the dew point and removing the carbon dioxide. Such a modification is seldom required, because the initial carbon content of the steel assemblies to be brazed is low (0.10 to 0.18% C) or because superficial decarburization can be tolerated. When control of carbon potential is required, a rich endothermic atmosphere usually is preferred.

The nominal composition of a rich exothermic-base atmosphere is given in Table 2. This atmosphere is produced by partial combustion of a hydrocarbon fuel, such as natural gas or propane, in air, using a generator that is equipped to control the ratio of air to fuel gas and thus to produce the desired composition. Detailed information regarding the generation of a rich exothermic atmosphere and the generator equipment employed is given on pages 71 to 73 in the article on Furnace Atmospheres, in Volume 2 of this Handbook.

For the application described in the following example, either an exothermic or an endothermic atmosphere would have been satisfactory; an exothermic atmosphere was selected, primarily because it was less expensive.

Example 544. Cost Advantage of an Exothermic Atmosphere in Copper Brazing of Low-Carbon Steel (Fig. 5)

The 12L14 steel pivot arm and the 1213 steel shaft that comprised the assembly shown in Fig. 5 could have been copper brazed in either an exothermic atmosphere or an endothermic atmosphere, with satis-

(a) Per 1000 cu ft of atmosphere; based on use of natural gas rated at 1000 Btu per cubic foot. For other fuel gases, multiply by: 2.0, for high-hydrogen artificial gas; 2.5, for medium-hydrogen, high-CO artificial gas; 0.4, for propane; and 0.3, for butane. (b) Values indicate number of parts of air to one part of gas (based on use of natural gas at 1000 Btu per cubic foot). (c) Dew point is about 10 F above temperature of cooling water; dew point may be reduced to +40 F by refrigeration, or to −50 F by adsorbent-tower dehydration. (d) Plus 250 cu ft per 1000 cu ft for heating gas. (e) 23.5 lb of ammonia per 1000 cu ft of atmosphere.

factory results in terms of both the quality of brazed joint and the metallurgical and surface condition of the steels after brazing. Consequently, the decision to use an exothermic atmosphere was based solely on the desire to reduce cost.

The initial cost of an endothermic generator with a capacity of 500 cu ft per hour was \$5665, whereas the cost of an exothermic generator of similar capacity was only \$3110. The cost of producing 1000 cu ft of gas was \$0.20 to \$0.25 for the endothermic gas and \$0.08 to \$0.12 for the exothermic gas, based on \$0.60 per 1000 cubic feet for natural gas, \$0.01 per kilowatt-hour for electricity, and \$0.10 per 1000 gallons for cooling water.

The pivot arm and shaft were degreased prior to assembly. Copper filler metal was applied in the form of a paste, as shown in Fig. 5. Assemblies were brazed at 2050 F under an exothermic atmosphere in an electric pusher-type furnace. Time in the brazing heat was 12 min, and production rate was 120 assemblies per hour.

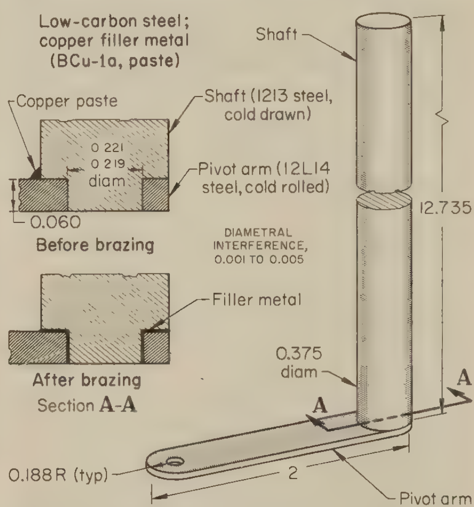

Fig. 5. Pivot-arm-and-shaft assembly that was furnace brazed in an exothermic atmosphere, rather than in an equally suitable endothermic atmosphere, to save atmosphere generator and production cost (Example 544)

Products of Combustion Through Charcoal. This brazing atmosphere, which was used in the application described in Example 551, is made by passing an exothermic gas (product of combustion of air and a hydrocarbon) through incandescent charcoal (see Table 2). The result is a gas having a low dew point (−15 F) and a higher carbon potential than the rich exothermic-base atmosphere.

Rich Prepared Nitrogen-Base Atmosphere. Although a rich exothermic-base atmosphere is most widely used in copper brazing of low-carbon steel, it is much less versatile than a rich prepared nitrogen-base atmosphere (AGA class 202). Because of its low dew point (−40 F) and the absence of carbon dioxide, this nitrogen-base atmosphere is more reducing than, and does not exhibit the decarburizing effects of, an unpurified exothermic atmosphere. It can be used whenever decarburization of steel assemblies is not permissible; hence it is used to protect carbon and low-alloy steels of medium carbon content. It is likely to cause partial decarburization of high-carbon steel and to carburize low-carbon steel. It is effective in protecting low-carbon steel from oxidation.

The nominal composition of a rich prepared nitrogen-base atmosphere is given in Table 2. A nitrogen-base atmosphere generator incorporating a scrubbing system is described on pages 74 and 75 in Volume 2 of this Handbook. The cost per unit volume of a prepared nitrogen-base atmosphere is roughly double that of an exothermic atmosphere. However, the main economic disadvantage lies in the high initial cost of generating and scrubbing equipment.

Endothermic-Base Atmospheres. The nominal compositions of a lean (AGA class 301) and of a rich (AGA class 302) endothermic-base atmosphere are given in Table 2. A lean atmosphere is generated by reacting lean mixtures of hydrocarbon gas and air in an externally heated chamber in the presence of a nickel catalyst.

By controlling the dew point of endothermic-base atmospheres, their carbon potential can be accurately controlled in the range from 0.20 to 1.30% C, making it possible to ensure equilibrium conditions for carbon and low-alloy steels of low, medium and high carbon content, thereby avoiding carburization and decarburization. The atmospheres are reducing, and thus protect against oxidation and promote wetting during brazing.

Generators for producing these atmospheres are considerably less complicated and less expensive than those required for producing nitrogen-base atmospheres; the operating costs for generating the gases are roughly equivalent. Endothermic-atmosphere generators and the reactions obtained in them with several different hydrocarbon fuels are described on pages 75 to 78 in Volume 2 of this Handbook, in the article on Furnace Atmospheres.

The principal disadvantages of endothermic atmospheres are their potential explosiveness when mixed with air and their sooting potential when dry, at the temperatures encountered in the cooling chambers of brazing furnaces.

Other Atmospheres and Vacuum. Other, more expensive atmospheres and vacuum are also suitable for the furnace brazing of steel. Because of the stability of surface oxides containing chromium, manganese, titanium, vanadium, aluminum and silicon, alloy steels containing a total of more than 2 or 3% of these elements can be fluxless brazed satisfactorily only in vacuum or in one of the strongly reducing atmospheres, such as dissociated ammonia or purified dry hydrogen (see Table 2 for compositions). Failure to reduce these alloy-containing surface oxides completely will prevent the filler metal from flowing in the joint, and so a flux may be necessary. Nickel or copper plating sometimes helps to prevent oxidation and improves wetting.

The more expensive atmospheres are rarely used without special justification, although in some plants that require them for brazing nonferrous alloys or for use in heat treating, they may be used for brazing steel simply because they are available and because justification for installing another atmosphere generator is lacking. In Example 545, a dry hydrogen atmosphere was used, and in Examples 553 and 563, dissociated ammonia was used.

Brazing With Copper Filler Metals

Copper is the preferred filler metal for furnace brazing of carbon and low-alloy steel assemblies without flux in reducing protective atmospheres. Significant amounts of two trace elements, arsenic and phosphorus, should be avoided, because they form brittle compounds in the brazed joint. The copper should be essentially free of arsenic, and if it was deoxidized with phosphorus, the residual phosphorus content should be low.

Filler Metals and Forms. There are three standard copper brazing filler metals, bearing the AWS designations BCu-1, BCu-1a, and BCu-2 (Table 3).

BCu-1 filler metal contains a minimum of 99.90% copper and a maximum of 0.10% of other elements. It is available in the form of strip, rod, and wire on spools.

BCu-1a filler metal contains a minimum of 99.0% copper and a maximum of 0.30% of other metallic elements. It is available as a powder in two standard sieve analyses, medium-1 and medium-2. It is applied as a powder in some applications, but is frequently mixed with a liquid vehicle and applied as a paste. In most applications, BCu-1 and BCu-1a are interchangeable.

BCu-2 filler metal is available in the form of a paste and contains a minimum of 86.5% copper and a maximum of 0.50% other metallics and 1.3% nonmetallic contaminants, including chlorides, sulfates, and matter insoluble

in nitric acid or soluble in acetone. The remainder is oxide. The paste is a suspension of particles of copper and cuprous oxide in a volatile vehicle.

Various proprietary pastes, identified by trade name and not covered by an AWS specification, are available commercially. These pastes are prepared with several different types of hygroscopic and nonhygroscopic vehicles, with different thinning, drying and spattering characteristics. In addition to the vehicle, some contain commercially pure copper powder only, and others contain powdered cuprous oxide only. Some pastes contain mixtures of copper powder and cuprous oxide; of copper powder, cuprous oxide and iron oxide; or of copper powder, cuprous oxide and iron powder. In general, pastes containing oxides require strongly reducing atmospheres to promote flow. Pastes containing iron or iron oxide are intended to fill joint clearances up to about 0.003 in. at brazing temperature.

The unalloyed copper filler metals (BCu types) should not be confused with the copper-phosphorus (BCuP) filler metals, which are never used for joining steel, or with the copper-zinc (RBCuZn) filler metals, which generally require the use of a borax – boric acid flux.

Joint Strength. A principal advantage of the copper filler metals used in the furnace brazing of steel is the high strength they impart to the brazed joints. The shear strength of copper joints in low-carbon steel generally ranges from 22,000 to about 31,000 psi, while the tensile strength ranges from 25,000 to almost 50,000 psi. The rotating-beam fatigue strength of these joints is also high; in one series of tests, copper brazed joints in low-carbon steel withstood 10 million cycles without fracture at stresses of about 12,000 psi. In all tests of joint strength, it is apparent that fit affects strength. When other variables are constant, a diametral interference fit of 0.001 in. will be slightly stronger than a slight diametral clearance fit (such as 0.0005 in.), and a diametral interference fit of 0.002 in. generally will be stronger still. Joint clearances and joint strength are discussed in greater detail in the section on Joint Fit and Design.

Carburizing of Copper Brazed Assemblies. The liquidus temperature of the copper filler metals is about 1980 F, and the recommended temperature range for brazing is 2000 to 2100 F. This range is safely above the temperature ranges for austenitizing and carburizing of carbon and low-alloy steels. Gas carburizing temperatures seldom exceed 1725 F. Carburizing a steel assembly after copper brazing, as was done in the following example, has no adverse effect on the brazed joint.

Example 545. Use of Copper Filler Metal To Braze a Steel Assembly That Was Later Carburized and Hardened (Fig. 6)

The components of the gear and clutch-ring assembly shown in Fig. 6 were joined by copper brazing, and were subsequently carburized and hardened. They were made of 9310 steel, and were brazed in a dry (−70 F dew point) hydrogen atmosphere because of the relatively high chromium content (1.00 to 1.40%) of the steel. The hydrogen atmosphere, which ensured the reduction of chromium-containing oxides on the surfaces to be brazed, was introduced at the top of a retort and exhausted through a sand seal at a rate of 15 retort volumes per hour. The retort was heated to the brazing temperature (2050 F) in a gas-fired batch furnace and was cooled in air to room temperature before the assemblies were removed. The filler metal was a paste made from copper powder (BCu-1a), and the brazing time was 30 min.

Preparation for brazing consisted in machining the mating surfaces of the joint to a light interference fit and blasting with cast iron grit.

After being brazed, the gear and clutch-ring assembly was gas carburized in a continuous furnace, using standard procedures, and hardened. Each assembly was then put through torque proof-testing.

Table 3. Copper Filler Metals Commonly Used in Furnace Brazing (AWS A5.8)

AWS classification	Minimum copper, %	Brazing temperature, F
BCu-1	99.90	2000-2100
BCu-1a	99.0	2000-2100
BCu-2	86.5	2000-2100

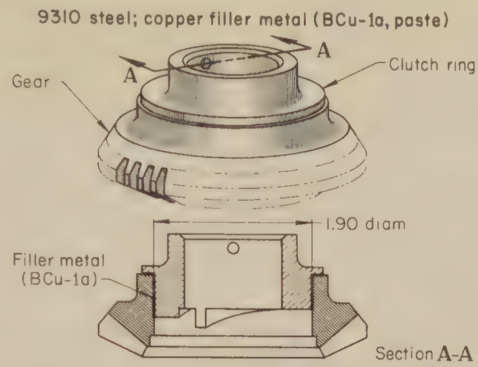

Fig. 6. Gear and clutch-ring assembly that was copper brazed in a hydrogen atmosphere, and later carburized and hardened (Example 545)

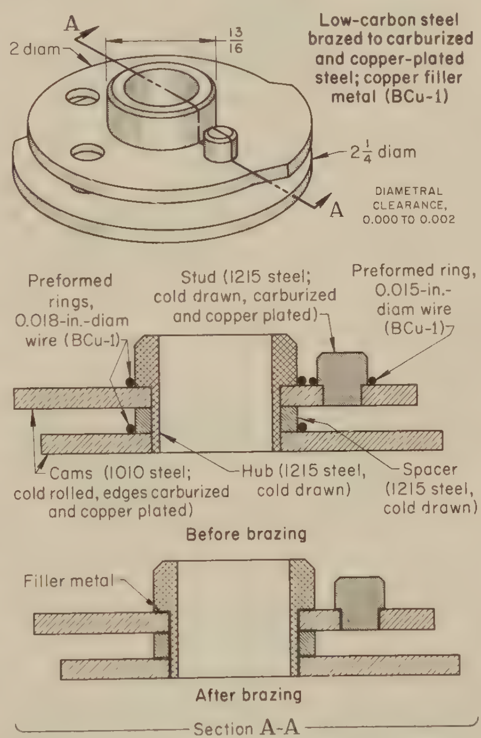

Fig. 7. Cam assembly that was selectively plated for protection of carburized surfaces during brazing (Example 546)

Brazing Carburized Components. A distinct advantage of furnace brazing with copper filler metal is that it permits carburizing before brazing, as well as after brazing. This means that only those components that require hardening need to be carburized. This is advantageous in some applications, such as the one described in the following example, which also gives procedures for satisfactory results.

Example 546. Copper Brazing of an Assembly Containing Carburized Components (Fig. 7)

Three of the five components of the cam assembly shown in Fig. 7 were carburized prior to assembling for copper brazing. The two 1010 steel cams were selectively carburized to produce a 0.020-in. case along the peripheral working surfaces, and the 1215 steel stud was carburized on all surfaces except the tenon portion to the same case depth. Surface carbon content of the case was about 1.1% after carburizing. This initially high surface carbon content compensated for subsequent diffusion during brazing and reheating for hardening. Surface carbon content after austenitizing in a neutral salt and oil quenching was not reported, but was satisfactory for the intended service. Resulting hardness was at least Rockwell 30N 79.

After carburizing, the cams and stud were thoroughly degreased and flash copper plated with a 0.0002-in.-thick coating. The spacer and hub, of 1215 steel, were also degreased, the five components were assembled for brazing, and copper filler metal in the form of preformed wire rings was preplaced as shown in Fig. 7. Diametral clearance ranged from 0.000 to 0.002 in. The assemblies were brazed at 2070 F in a 100-kw electrically heated mesh-belt conveyor furnace (12-in.-wide belt) under a lean endothermic atmosphere. The carbon potential of the atmosphere was maintained between 0.3 and 0.4% C. Brazing time was 11 min per piece and production rate was 1000 assemblies per hour.

Originally, the copper plating had been applied only to the components that had not been carburized (the hub and spacer), in order to protect them from acquiring a hard, difficult-to-machine surface during brazing in an atmosphere of high carbon potential, which was required to keep the carburized components from decarburizing. Copper plate approximately 0.0005 in. thick was needed to protect the surfaces, and it ran during brazing, forming puddles that were difficult to remove. Therefore, it was decided to use an atmosphere that was compatible with the bare noncarburized components, and to copper plate only the carburized components. With the atmosphere of lower carbon potential, a 0.0002-in.-thick copper plate was sufficient to prevent decarburizing of the components to be hardened. The desired results were obtained: use of the thinner copper plate virtually eliminated puddling of the copper, and the atmosphere with the lower carbon potential effectively eliminated sooting in the furnace and in the generator.

Cost of Brazing With Copper vs Silver Alloy Filler Metal. Copper filler metals have the advantage of low cost, especially when compared to filler metals containing silver. Depending on the silver content, the cost (in 1971) of silver alloy filler metal in wire form ranges from 10 to 20 times the cost of an equal volume of copper filler metal, and thus is a significant portion of the total cost of silver brazing. The table that follows shows some typical 1971 costs for butt-end preformed rings of BAg-1, which has a nominal silver

Table 4. Results of a Cost Study To Determine Saving or Loss by Use of Cu-Zn-Ag Instead of Copper Brazing Filler Metal To Increase Life of Mesh Belts by Brazing at Lower Temperature (Example 547)

Item	Filler metal: Copper	Filler metal: Cu-Zn-Ag alloy(a)	Cost saving (+) or loss (—)
Filler-metal consumption per year, lb	1000	1000	...
Cost per pound of filler metal(b)	$ 0.52	$ 5.00	...
Filler-metal cost per year	$ 520	$5000	—$4480
Mesh-belt cost	$3000	$3000	...
Belt life, months(c)	9	18	...
Belt cost per year	$4000	$2000	+$2000
Net loss by use of Cu-Zn-Ag filler metal			—$2480

(a) 53% Cu, 38% Zn, 9% Ag. (b) Using 0.018-in.-diam wire, purchased in 500-lb lots. (c) At brazing temperatures of 2050 F for copper and 1850 F for Cu-Zn-Ag brazing filler metal.

content of 45% and is one of the commonly used silver alloy filler metals:

Ring ID, in.	Cost per butt-end ring formed from wire diameter of: 0.032 in.	0.040 in.	0.062 in.
0.500	1.1¢	1.6¢	3.5¢
0.750	1.5	2.3	5.0
1.000	1.9	2.9	6.5

Costs are based on prices per troy ounce of $1.40 for the 0.032-in.-diam wire, $1.32 for the 0.040-in.-diam wire, and $1.22 for the 0.062-in.-diam wire, plus 0.2¢ per ring for forming and cutting, in lots of 10,000 rings.

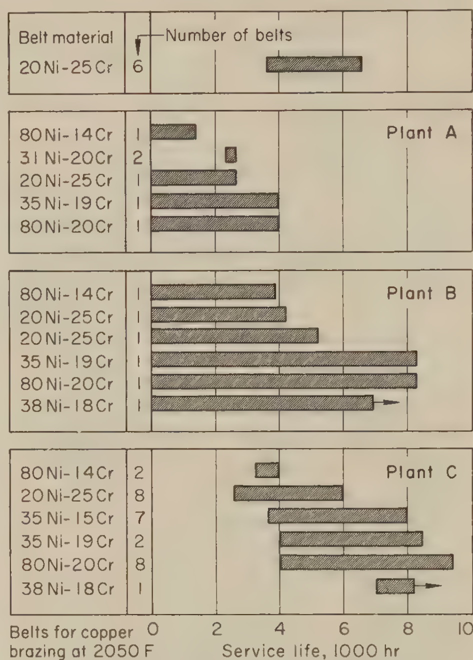
An additional cost for using silver alloy filler metal in furnace brazing is the cost of the flux. For example, the cost of the flux commonly used in brazing with BAg-1 filler metal is about $1.50 per pound. If one pound of flux is used in making 300 joints, the cost of flux per joint is about 0.5¢. However, in many operations, to reduce labor costs, two to three times the minimum amount of flux is applied, at two to three times the material cost. To this must be added the labor cost for applying the flux and for washing the assembly after brazing to remove the flux, and the cost of disposing of the flux-contaminated wash water.

Although furnace brazing using copper filler metal is likely to shorten the life of furnace components and to increase maintenance costs, because of the higher brazing temperatures, the higher cost for silver alloy filler metals, and the cost of flux attack on furnace components (see also Examples 548 and 564), make it the more costly process, as shown in the following example.

Example 547. Cost Study of Furnace Brazing Using Copper and Silver Alloy Filler Metal (Table 4)

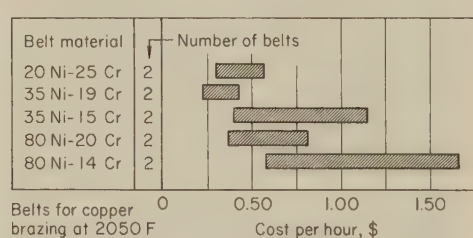
A major maintenance cost of the copper brazing operations at one plant was the replacement of the 12-in.-wide heat-resisting alloy mesh belts used in the five production furnaces. As part of a cost-reduction program, a study was made to determine the possibility of reducing this cost. On the basis of published data that indicated an approximate 50% increase in belt life for each 100 F reduction in operating temperature below 2050 F, the potential benefits of substituting a lower-melting filler metal for copper were investigated.

Laboratory tests with production assemblies indicated that one of the less expensive silver-containing alloys (53% Cu, 38% Zn and 9% Ag, with a melting, or liquidus, temperature of approximately 1400 F) had satisfactory joint-filling properties. However, when this alloy was tried, normal production volume could not be maintained unless the furnace heating chambers were operating at 1850 F, even though a lower temperature would have been adequate for melting and flow of the filler metal. In addition, tests of brazed joints showed an 18% reduction in torque strength, as compared to copper brazed joints, restricting the use of the silver alloy filler metal to parts with relatively low stress levels.



The six belts in the top graph had B 43-11-10 fabricated weave. The belts of plant A had RR 18-17-10 fabricated weave, and those of plant B, RR 23-22-12 fabricated weave. Bars with arrows indicate belts that were still in service at the end of the survey period.

Fig. 8. Service life of woven belts in copper brazing furnaces operating at 2050 F



Mesh belts were of reinforced RR 18-17-10 weave. High cost of 80Ni-14Cr belts was caused by early mechanical failure that resulted from parts sticking to the belts.

Fig. 9. Comparison of costs per operating hour for mesh (woven) belts of five different materials, used in copper brazing furnaces operating at 2050 F

Despite these limitations, the 200 F reduction in brazing temperature suggested a 100% increase in belt life, and preliminary cost estimates were prepared to weigh this potential saving in maintenance cost against the higher cost of the filler metal. The estimates, shown in Table 4, indicated a cost increase of approximately $2500 at the production rates required, not including additional costs of flux, flux application, flux removal, and flux attack on furnace components. As a result, no further consideration was given to using silver alloy filler metal for brazing applications in this plant.

Mesh belts are used in furnaces of various capacities and for loads of various sizes. Figure 8 shows service life for rod-reinforced mesh belts made from several different alloys and used in copper brazing furnaces at 2050 F.

Load-density limits for mesh belts are established mainly by operating temperature, length from the loading position to the discharge end of the heating chamber, belt alloy, cross-sectional area of the belt, the brazing atmosphere used, and an estimate of acceptable life. It is essential that the mesh does not become crushed, either from excessive loading or from parts dropping into the mesh. For an operating temperature of 1450 to 1650 F, a load range of 16 to 140 lb per square foot is usually permissible, but the allowable loading decreases to about 4 to 30 lb per square foot when the temperature is increased to 2050 F.

The performance of certain alloys used for mesh belts is often difficult to explain. For example, in Fig. 8, belts made of 35Ni-19Cr and of 80Ni-20Cr gave the same life in plants A and B. These service data show that use of a high-alloy, high-cost material may not result in lowest hourly operating cost.

In addition to the tensile loading that a mesh belt receives, several other factors influence its life in a furnace.

1. Composition of the oxide coating on the surface affects the amount of friction at the loop connections.
2. Friction at rubbing joints has a significant effect on the degree of pressure welding, and may influence life.
3. Stretching during service changes the contour of the loops, and increases the stiffness of the belt, as does camber or bowing of the cross-rods. A reduction in flexibility, such as is generally encountered when the alloy wire becomes old and brittle, can hasten failure during the return trip of the belt over drive rolls, even though this repeated stress takes place at room temperature.
4. Use of fluxes will reduce belt life, because fluxes spill on the belt and promote deterioration.
5. The contour of the loops and the method of joining at the edges of the belt are equally important. Certain patterns or weaves will perform better on a specific furnace and will yield longer belt life.

Figure 9 also shows that an alloy of lower initial cost may also be less expensive when judged by cost per service hour; two of the lower-alloy materials were superior to the 80% nickel alloys. From a practical standpoint, data on cost per service hour may be incomplete. Other factors should be considered, notably: (*a*) labor cost of repairs, (*b*) loss of productivity during downtime, and (*c*) the possibility of damage to other components if the belt fails (most belts that have been in use for a reasonable period of time are replaced before they break).

Elimination of Flux. Copper filler metals, when used in conjunction with a suitable protective atmosphere in the brazing of steel, are self-fluxing by virtue of the ability of the atmosphere to reduce surface oxides and thereby to promote the flow of filler metal. Fluxes increase brazing costs and contaminate

and corrode heating elements and other furnace components. The relative importance of flux contamination varies considerably among applications. In applications such as that described in the following example, flux contamination may become a dominant factor in the selection of a filler metal.

Example 548. Change From Silver to Copper Brazing To Avoid Contamination of Furnace by Flux (Fig. 10)

Originally, the cam-and-sleeve assembly shown in Fig. 10 was joined by torch brazing, using a silver alloy filler metal, but distortion caused by uneven heating was excessive. When the process was changed to furnace brazing with silver alloy filler metal (BAg-1) and flux (AWS 3A), distortion was reduced, but the contamination and corrosion of furnace rails and exposed heating elements by the fluorides in the flux and the zinc vapors from the silver alloy were objectionable.

Furnace brazing with copper filler metal in a protective atmosphere containing 30% CO, 16% H_2, rem N_2 eliminated the need for a flux (and thus eliminated flux damage). Because a tighter joint fit was used with copper brazing, dimensional requirements were met more easily.

The cam was made of half-hard 1020 steel, and the sleeve, of 1113 steel. The dimensional requirement for both the hole in the cam and the mating diameter on the sleeve was 0.625 + 0.001, − 0.000 in. After being cleaned, the components were assembled in a fixture that held the sleeve in the proper orientation while it was staked; a preformed ring of 0.020-in.-diam BCu-1 wire was placed over the sleeve (see Fig. 10).

The assemblies were brazed at 2050 F in an electric pusher-type furnace with a heating chamber 12 by 36 in. by 8 in. high. Brazing time was 15 min, and production rate was 60 assemblies per hour.

Selection of Filler-Metal Form. Copper filler metal is available in several forms, including wire, strip, special preforms, powder, and a variety of pastes. Occasionally, copper that is to serve as filler metal is deposited on the base metal by electroplating. Selection of the preferred form of filler metal is usually based on joint design, ease of placement in assembly, ability to retain a fixed location during transit through the furnace, and production quantities required. The next three examples discuss the reasons for selecting two forms of filler metal — paste and electroplating — on the basis of the application requirements.

Example 549. Use of a Paste Form of Copper Filler Metal Because of Low Production Volume (Fig. 11)

In the business-machine assembly shown in Fig. 11, the 1215 steel block was projection welded to the 1010 steel arm and then the joint area surrounding the projection weld nugget was furnace copper brazed to provide the strength required in service. In selecting the form of copper filler metal, several factors had to be considered. Production volume was relatively low, and therefore the cost of preforming special copper wires to the desired configuration could not be justified. Placing a piece of wire at the joint would have been unsatisfactory because the wire could be moved out of position by vibration during transit through the furnace. Hand crimping the wire would have prevented displacement, but crimping would have been time consuming and difficult. Mechanical precrimping could not be justified on the basis of production quantity. Under the circumstances, and because fillets in the joint area were not objectionable, filler metal in

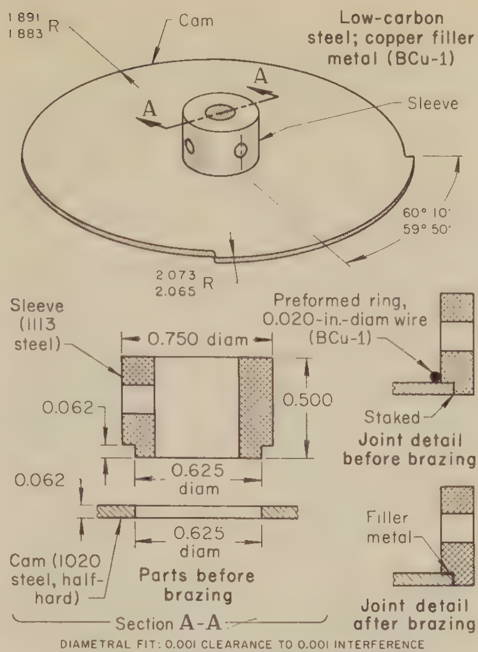


Fig. 10. Cam-and-sleeve assembly that was furnace brazed using copper filler metal, to minimize warpage and eliminate use of flux (Example 548)

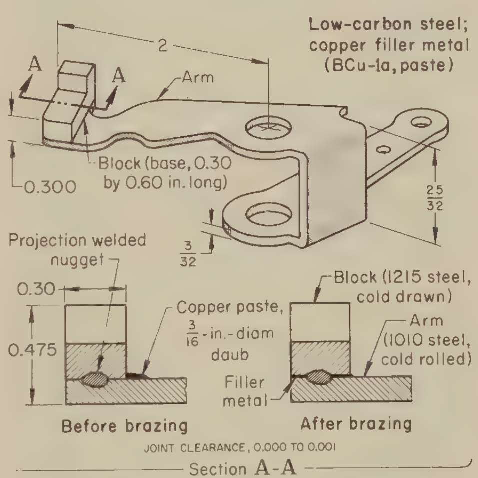

Fig. 11. Business-machine assembly to which copper filler metal was applied as a paste (Example 549)

the form of a copper paste proved most economical and easiest to apply. The paste was applied to one side of the joint in the form of a daub about 3/16 in. in diameter (see Fig. 11).

The assemblies were brazed at 2070 F in a 100-kw electrically heated mesh-belt conveyor furnace (12-in.-wide belt), in an endothermic atmosphere. Time in the heating chamber was 9 min, and the production rate was 900 assemblies per hour.

Examples 550 and 551. Use of Copper Plating as a Filler Metal To Control the Volume of Copper in Brazed Joints

Example 550 — Plate-and-Stud Assembly (Fig. 12). The small size of the two studs and adjacent joint areas in the plate-and-stud assembly shown in Fig. 12 required close control of the amount of copper in the brazed joint. Copper paste applicators could not deliver the required volume with enough accuracy. Manual placement of wire rings was not feasible because the small diameters of the wire and ring would make placement slow and tedious. Automatic ring placement was feasible, but could not be justified because of low production rate. The stud tenons could have been dipped in copper paste before assembly by press fitting, but dipping would have been slow and messy unless mechanized — an expense that was not justifiable.

Copper plating the studs in a barrel proved to be feasible and economical. Plating time and operating conditions had to be accurately controlled to ensure an optimum thickness of copper — enough to fill the joint without developing an excessive fillet at the joint or copper puddles in critical areas. Plating thickness was controlled by a drop test to 0.00012 to 0.00023 in. Diametral clearance between stud and plate was held to 0.0000 to 0.0015 in.

The degreased components (1010 steel plate and 1215 steel studs) were assembled and then brazed in a 100-kw electric mesh-belt conveyor furnace (12-in.-wide belt), in an endothermic atmosphere. The brazing time was 8 min at 2070 F. Production rate was 2200 assemblies per hour.

Example 551 — Hub-and-Lever Assembly (Fig. 13). The small assembly shown in Fig. 13, consisting of a 12L14 steel hub and a 1020 steel lever, was furnace brazed using 0.0003-in.-thick copper plate on the hub as the filler metal. Plated filler metal was selected because copper paste could not be

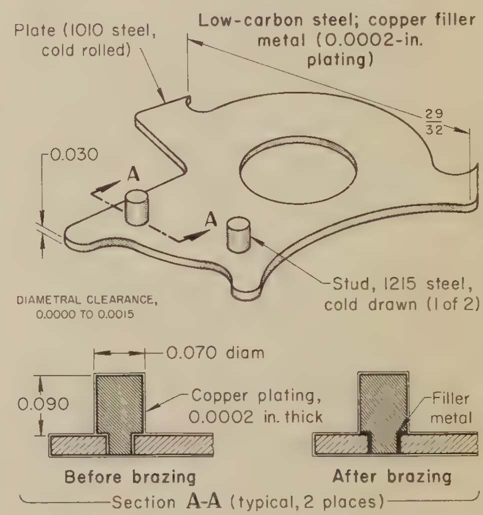

Fig. 12. Plate-and-stud assembly with small brazed joints to which filler metal was applied by plating (Example 550)

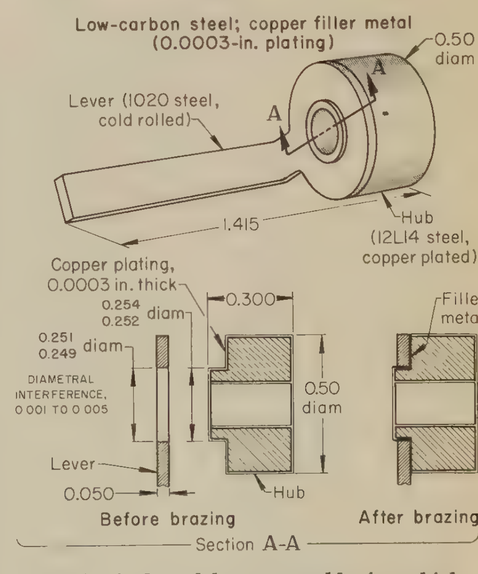

Fig. 13. Hub-and-lever assembly for which close control of volume of brazing filler metal was provided by plating (Example 551)

applied with equivalent uniformity of volume and because a preplaced copper wire ring, although otherwise satisfactory, might have fallen from the joint location during transit through the furnace.

The plated hub and the vapor degreased lever were assembled with a diametral interference of 0.001 to 0.005 in. and were brazed in a protective atmosphere containing 30% CO, 16% H_2, rem N_2 in a pusher-type furnace at 2050 F. Brazing time was 10 min, and the production rate was 400 assemblies per hour.

Cleaning and Surface Preparation for Brazing

Cleaning is almost always advisable before brazing because the presence of oil, grease, pigmented drawing lubricants, excessive amounts of oxide, and other surface contaminants in or near the brazed joint will have a deleterious effect on the soundness and strength of the joint. Some contaminants will interfere with the wetting action, so that normal flow of molten filler metal in the joint will be prevented.

Both chemical and mechanical cleaning methods are used to clean steel components and assemblies for brazing, but chemical methods are the more widely used. Chemical methods include akaline cleaning, solvent cleaning, vapor degreasing, and sometimes acid pickling. The mechanical methods most commonly used are dry and wet abrasive blast cleaning. Other cleaning methods, if they prove satisfactory, are employed largely because the necessary equipment is available. If warranted, machining or grinding may be used to obtain the necessary joint cleanness, and to ensure satisfactory wetting.

Chemical Cleaning Methods. Alkaline cleaning, including soak, spray and barrel cleaning, is widely used for removing oily, semisolid or solid soils from steel components before furnace brazing. It is generally satisfactory for removing most cutting and grinding fluids, grinding and polishing abrasives, and some pigmented drawing compounds. The solutions, methods, equipment requirements, advantages and limitations, as well as costs, are described in the article on pages 317 to 325 in Volume 2 of this Handbook.

Solvent cleaning is capable of removing oil, grease, loose metal chips, and other contaminants from steel components. Parts are immersed and soaked in a common organic solvent. Spray methods can also be employed. The solvents, process variables, equipment, and limitations of solvent cleaning are described in the article on Solvent Cleaning, pages 330 to 333 in Volume 2 of this Handbook.

Vapor degreasing, a cleaning process used in a number of the examples in this article, employs the hot vapors from a boiling chlorinated hydrocarbon solvent to remove surface contaminants such as oils, greases and waxes. To supplement the vapor, some degreasing units are equipped with facilities for immersing the work in the hot solvent or for spraying with clean solvent. Solvents, procedures, equipment, costs, and other aspects of the cleaning process are described in the article on Vapor Degreasing, pages 334 to 340 in Volume 2 of this Handbook.

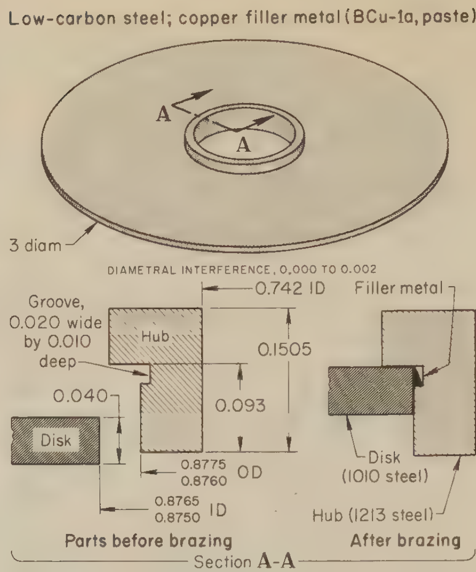

Fig. 14. Brazed type-wheel assembly for which cleaning method was changed from tumbling in abrasive oxides to belt sanding to improve flow of filler metal (Example 552)

Mechanical Cleaning Methods. As previously noted, mechanical methods are less widely used than chemical methods in cleaning for brazing. However, they are usually preferred for removing heavy scale and may be indispensable in removing the more tenacious lubricants, such as a pigmented drawing compound. Mechanical methods are also useful in surface preparation that involves abrading or roughening, which may be required on a very smooth surface to promote wetting and filler-metal flow.

In dry grit blasting, the grits used on carbon and low-alloy steels consist of angular metallic particles of chilled cast iron or of hardened cast steel. Wet blasting employs many different kinds and sizes of abrasives suspended in a liquid carrier. Certain ingredients in the liquid carrier, such as rust inhibitors and the minerals in the water, may adversely affect the wetting action in brazing, and could require an additional cleaning process to remove all traces of liquid carrier from the work. The abrasives, equipment and procedures used in both dry and wet blasting are described in the article on Abrasive Blast Cleaning, pages 364 to 370 in Volume 2 of this Handbook.

Special processing problems, or a high rate of production, may require the use of other mechanical cleaning methods, such as tumbling, belt sanding, grinding, wire brushing, and machining. In the next example, belt sanding proved to be the optimum cleaning method for the application.

Example 552. Substitution of Belt Sanding for Tumbling as a Cleaning Method for Furnace Brazing (Fig. 14)

The 1010 steel disk and 1213 steel hub that comprised a type-wheel assembly (see Fig. 14) were cleaned by belt sanding prior to assembly and brazing. Originally, the components had been tumbled in abrasive oxides to deburr and clean them in the same operation, but tumbling resulted in surface contamination that caused the molten copper filler metal to gather in droplets rather than to flow into the joint. With belt sanding, there was no surface contamination and the filler metal flowed properly.

After belt sanding, the components, which were machined to provide tenon-hole diametral interference of 0.000 to 0.002 in., were assembled by staking. Copper filler metal was applied in paste form. Assemblies were brazed in a mesh-belt conveyor furnace (12-in.-wide belt) at 2050 F, in an endothermic atmosphere. Total heating and cooling time was 30 min. Brazed assemblies were subsequently carburized. The brazing production rate was 125 disk-and-hub assemblies per hour; 250,000 assemblies were produced annually.

The joint design used for the assembly discussed in the foregoing example is not considered good (specifically, the 0.020-by-0.010-in. groove). The groove was initially intended to contain a filler metal wire and was not redesigned when a change was made to paste. However, an acceptable joint was made by the procedures described.

Stop-offs

Under ideal conditions, the filler metal flows by capillary action and, in so doing, completely penetrates the joint. In practice, flow may not stop when the joint is filled, and filler metal may flow onto areas where it is not wanted. For example:

1. In brazing a threaded stud into a part, the filler metal is likely to follow the threads and render them out-of-tolerance.
2. Support points on fixtures used in furnace brazing may become wetted by the filler metal, producing an unwanted braze and perhaps resulting in loss of the fixture and assembly, because it may be impossible to separate them without damage.
3. Some parts, such as turbine and compressor brazements, are designed to close tolerances and excess filler metal may be dimensionally objectionable.
4. Tubular assemblies, particularly small capillary tubes (1/16-in. ID or less), can easily become partly or completely blocked with filler metal.
5. Excess filler metal may be unacceptable because of appearance.
6. In production brazing, where it may be necessary to use more filler metal than called for to allow for variations in fit-up between parts, some joints will have excess filler metal, which will flow away from the joint area.

Stop-off Materials. For brazing carbon and low-alloy steels in the more commonly used atmospheres, such as exothermic-base, milk of magnesia painted on the appropriate areas is an effective stop-off. Also, painting fixtures with a water solution of chromic acid and then heating them to the brazing temperature renders them resistant to wetting by the filler metal, because a thin layer of chromium oxide forms.

For brazing in a hydrogen atmosphere or in vacuum, the two proprietary materials used are composed of oxides of aluminum, titanium, magnesium, and sometimes of other elements. One is fast drying, and behaves much like a commercial lacquer, the thinners being commercial lacquer thinners such as acetone. The second is a nonwicking type, composed of oxides in a gelled vehicle, that does not settle out on standing; this type dries slowly.

Methods of Applying Stop-off. For large areas, the use of a paintbrush or

a paint roller is a satisfactory method of applying stop-off. This method is used to protect touch points of metal fixtures. Often, it is advisable to repaint the fixture prior to each use, because some stop-off may crack off during each heating cycle.

The use of an artist's brush is ideal for precision application of fine areas of stop-off, although the operation is time consuming and requires considerable skill.

Use of a medical syringe makes it possible to obtain extremely fine detail in stop-off. Needles of 0.010-in. ID are often used. With a small needle, a drop of stop-off can be applied at a precise point. Hypodermic syringes are not suitable for use with fast-drying stop-offs, because the needles soon become clogged.

With the fast-drying type of stop-off, there is always danger that some of it will inadvertently run into the joint area. If this happens, the assembly must be taken apart and all stop-off must be removed.

A nonwicking stop-off can be applied by conventional equipment designed for application of liquid plastics, paste brazing alloys, and other organic compounds. It will remain stable over long periods of time, and will not clog the valves and tubing in the system.

Assembly for Brazing

The component parts of an assembly to be furnace brazed must be assembled in an essentially fixed position before entering the furnace, and they must be capable of maintaining this position throughout brazing and cooling. The filler metal, a part of the assembly, must be preplaced in the proper location and in the most convenient form, and it must maintain this location.

Self-jigging is the method of assembly in which the component parts incorporate design features that will ensure that the components, when assembled, will remain in proper relationship throughout the brazing cycle without the aid of auxiliary fixtures. This is the preferred method of assembly, as it eliminates the initial and replacement cost of auxiliary fixtures and the cost of heating them during brazing, and it usually is a more sure method of holding the components. Self-jigging can be accomplished by several methods, including gravity locating, interference or press fitting, knurling, staking, expanding, spinning, swaging, crimping, thread joining, riveting, folding, peening, and tack welding, as shown in Fig. 15. In addition to the self-jigging techniques described in this section, numerous applications of self-jigging are given in the examples in this article.

Gravity Locating. Perhaps the simplest method of assembling two components is to rest one on top of the other with the brazing filler metal either wrapped around one component near the joint (Fig. 15a) or placed between components (Fig. 15b). The principal disadvantage of gravity locating may be the lack of a dependable means of orienting the components or keeping them from moving in relation to one another. Nevertheless, some production components are assembled in this manner, especially those in which the upper component is relatively heavy.

Interference or press fitting, which requires expansion or contraction of mating component surfaces, provides a very tight fit — sometimes called a "tight press fit". Interference fitting is illustrated in Fig. 15(c) and (d). In Fig. 15(c), the cup has an inside diameter that is smaller than the mating projection of the underlying plate. The extent of interference seldom exceeds about 0.001 in. per inch of diameter, up to about 3-in. diameters. Nevertheless, most interference fits require considerable force to achieve assembly, a force generally provided by an arbor press or similar tool. Thus, an interference fit is a press fit.

Lighter interference fits, such as that shown in Fig. 15(d), may provide zero clearance or a very slight gap between the mating surfaces of components. These, too, require some external force, such as that provided by an arbor press, to achieve assembly. Fits with zero clearance are referred to as "size-to-size" fits. Some method is used to prevent slippage when the components are heated in the furnace, particularly if the joint has a vertical axis. As shown in Fig. 15(d), a shoulder on one of the components can be used to ensure stability.

Knurling. In high-production manufacturing, there will be considerable variation in joint clearance among the assemblies being brazed. Typical brazed assemblies in which a round male member is fitted to a female member are subject to either of two conditions: (*a*) the male part is off-center, thus allowing all of the diametral clearance on one side, or (*b*) the male member is out-of-round, so that all of the clearance will be on two opposite sides with no clearance (or even interference) on the other two sides.

Knurling the end of the male member (Fig. 15e) is sometimes a way of correcting the conditions described above and obtaining uniformity among brazed joints. Often, knurling can be done during machining of the part, thus adding very little to the cost. If knurling must be done in a secondary operation, the extra cost often can be balanced against the cost of the rejects that would be encountered if knurling were not done.

When the male member is tubular, prick punching may be substituted for knurling. Usually two rows of prick punch marks near the end of the male member are sufficient. Prick punching is easily done, but since it involves a secondary operation, the cost must be justified.

Staking. Figure 15(f) shows how staking will effectively lock two components in position. Burrs are turned up on the shaft by driving a punch into it. This method, of which there are a number of modifications, is commonly used to retain the orientation of such assemblies as cams, levers and gears on shafts or on common hubs. It is sometimes a substitute for tack welding, knurling or interference fitting.

Expanding. This method is commonly used in assemblies of tubes to tube sheets. The tubular component is pressed into a header sheet and expanded in the hole to lock the assembly, as shown in Fig. 15(g). Rings of brazing filler metal can be placed over the tube before or after the expanding operation. To avoid obtaining a mere line contact in expanding, a leader can be placed on the expanding tool to project into the tube and support the tube wall while the end of the tube is being flared.

Spinning. When the diameter of a hole in an assembly may not be altered during assembly, as when a hub is fastened to a lever, the assembly can be locked together, as shown in Fig. 15(h), by spinning in a

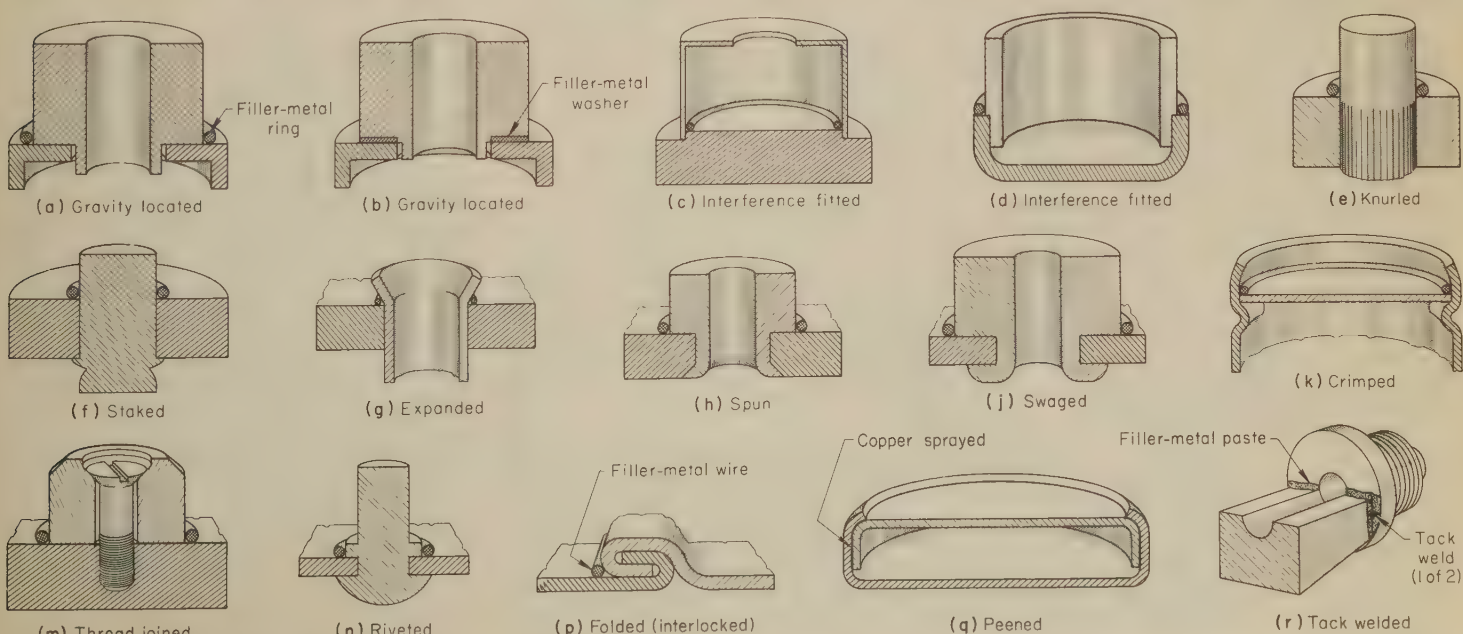

Fig. 15. Assemblies illustrating the use of several methods of self-jigging, to hold components together for furnace brazing

riveting machine. The same result can be obtained by flaring the tenon in a press. Tolerances for the punched hole and tenon must be held closely, to ensure the close joint clearances required for brazing. The punched hole must be chamfered, as shown in Fig. 15(h), to allow room for the spun or pressed end of the tenon. The spinning method of assembly is used for parts for various types of business machines, many of which were formerly assembled by cross drilling and pinning the hubs.

Swaging. An inexpensive and effective method of assembling a spud in a hole in a hollow body is to swage it in place, as shown in Fig. 15(j). This method is acceptable when it is not necessary to maintain accuracy of the diameter of the hole in the hub and when the projection on the flange can be tolerated. The principal advantage of swaging is that close tolerances do not have to be held on the tenon or the punched hole because the swaging operation forces the components into intimate contact. In addition to other applications, swaging has been used to assemble a valve body in a float chamber for refrigerators. The resulting bond after furnace copper brazing is strong, tight, leakproof, and capable of withstanding high pressure.

Crimping. Figure 15(k) shows the assembly of a disk, shell, and copper filler-metal ring in which the disk and ring are held in place by crimping the end of the shell. Also shown is an inexpensive method of forming "stoppers" against which the disk is located; these stoppers consist of three or four indentations around the shell.

In general, it is preferable to set an assembly of this type on end in the furnace so that the filler metal will flow downward through the joints. However, if the tubular component is long, the assembly must be laid on its side to clear through the furnace, and so an oversize ring of hard copper wire filler metal that can be sprung in place close to the joint is used. If the diameter of the tube is 2 in. or more, the filler-metal wire and adjoining steel surfaces should be coated with copper powder paste, which will harden and prevent the wire from sagging away from the joint at the top as the assembly is heated. The paste also provides an auxiliary supply of filler metal.

Thread joining has been used for assembling components of replacement punch holders for die sets used in punch presses.

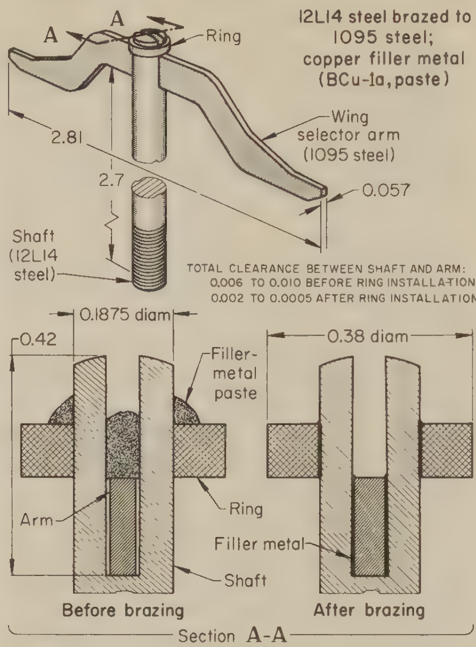

Fig. 16. Use of a press-fit ring to obtain self-jigging in a shaft and selector-arm assembly (Example 553)

As shown in Fig. 15(m), the shank is held in place on the punch-holder plate by a screw. Because drilling and tapping are required, this method of assembly is generally limited to small production quantities.

Riveting, illustrated in Fig. 15(n), is a modification of the spinning and swaging methods that uses a rivet as part of the assembly. It is widely used to assemble the vanes to the outer disks of fan wheels before furnace copper brazing. The combination of riveting and copper brazing markedly extends the service life of the assembly.

Folding or Interlocking. Several methods and designs of folding or interlocking can be used to secure joints, such as that shown in Fig. 15(p). These methods are widely used in the manufacture of brazed tubing or tubular assemblies. Copper filler metal is supplied either in the form of copper plating or by wedging a copper wire at the base of the joint. Capillary action will draw the filler metal to all areas of the joint.

Peening. Assembly of two hollow shells by the peening method is shown in Fig. 15(q). The stamped components are pressed together, and the outer shell is peened with an air hammer along the periphery. To apply filler metal to an assembly of this type, copper can be sprayed on the joint interfaces before assembly, using an oxy-acetylene spray gun.

Tack Welding. Prior to copper brazing, the tip and shank of the electrode holder for an atomic-hydrogen welding torch were assembled by tack welding, as shown in Fig. 15(r). Filler metal consisted of a small amount of copper powder paste daubed around the joint. Any oxide formed during tack welding was reduced by the protective atmosphere during furnace brazing.

The tack welding method of assembly usually requires careful investigation to determine the most strategic point or points for placing the weld. For economy, the number of tack welds per assembly should be held to a minimum.

Examples of Practice. Methods of assembly that involve pinning, wedging or winding are also feasible in some applications, and there are a great many modifications and combinations of conventional methods. In the example that follows, the interference-fitting method of assembly was modified by the use of an auxiliary ring to clamp the major components in position, rather than interference fitting one to the other.

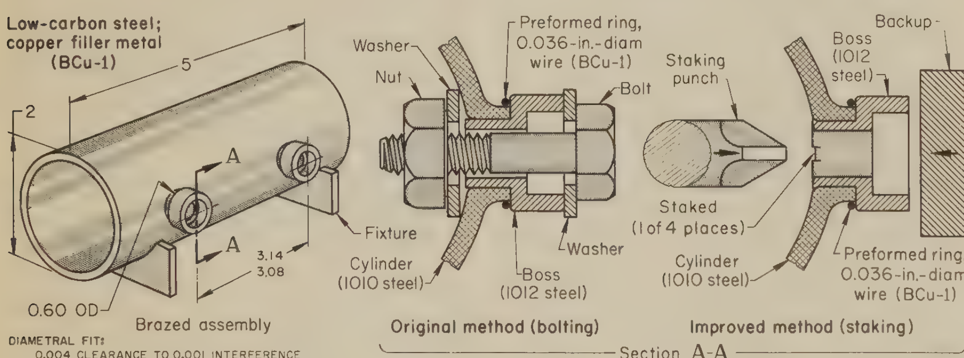

Fig. 17. Change from bolting to staking as the method of holding fuel bosses to a fuel cylinder prior to furnace brazing. Improved method reduced manufacturing cost by 30% and increased production rate by 150%, compared with original method (Example 554)

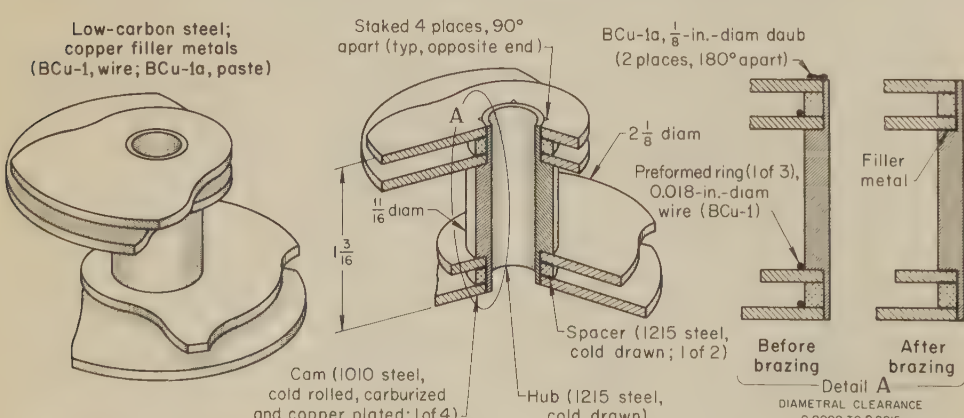

Fig. 18. Multiple-cam assembly for which the method of self-jigging for brazing was changed from riveting to square staking to eliminate radial stress that caused warpage (Example 555)

Example 553. Use of a Press-Fit Ring To Obtain Self-Jigging (Fig. 16)

The 12L14 steel shaft and 1095 steel selector arm shown in Fig. 16 presented a problem in assembly and in the application of brazing alloy. The problem was solved by increasing the depth of the slot in the top of the shaft 3/16 in. beyond the initial depth, permitting the selector arm to seat farther into the slot and providing clearance at the top of the shaft for placement of a press-fit ring. Joint clearance was 0.003 to 0.005 in. on each side of the selector arm before application of the ring. Over-all clearance was reduced to 0.0005 to 0.0020 in. after placement of the ring. This arrangement held the selector arm tightly in position. Filler metal was applied in the form of a paste made from BCu-1a powder (99.0% min Cu). The paste was applied above and around the brazed area to permit flow downward into the joint. The ring was brazed in place.

Before brazing, the assemblies were placed in brazing jigs, which consisted of blocks of graphite 12 by 5 by 3 in. thick containing 40 holes drilled to accommodate the shafts of 40 assemblies. The assemblies were brazed in a mesh-belt conveyor furnace, at a belt speed of 6 in. per minute. The brazing temperature was 2050 F, and the protective atmosphere was dissociated

ammonia. After cooling in the cooling chamber under a protective atmosphere, the assemblies were immersed for 1 hr in a chromic acid solution to remove excess copper. With this setup, it was possible to braze 1200 assemblies per hour, although the preparation rate was only 400 assemblies per hour.

After cleaning, assemblies were inspected by metallographic examination on a sampling basis for completeness of penetration, decarburization, and defects such as voids. Absence of decarburization was important because the 1095 steel selector arm was highly susceptible to decarburization.

Because it requires no special tooling, bolting is an inexpensive means for jigging assemblies in some applications, particularly for low production, but because of the manual labor required to apply and remove the bolt, it may be expensive in others. In the following example, the substitution of staking for bolting resulted in a large reduction in cost and production time.

Example 554. Substitution of Staking for Bolting To Reduce Costs of Assembling Components (Fig. 17)

Manufacturing cost was reduced by 30% and production rate was increased from 100 to 250 assemblies per hour when staking replaced bolting as the method of holding 1012 steel fuel bosses in a 1010 steel fuel cylinder prior to copper brazing. Figure 17 illustrates both methods and shows the completed assembly after brazing.

Staking was done in a press, with the offset staking punch entering the fuel boss from inside the cylinder while the boss was held firmly in place by an external nesting tool.

Assemblies were brazed at 2040 F in a mesh-belt conveyor furnace, in an endothermic atmosphere. Brazing time was 11 min; time in the cooling chamber was 29 min. A preformed ring of 0.036-in.-diam copper wire (BCu-1) was used for the filler metal.

Riveting necessarily imposes high stresses on the components being riveted; in many applications, these stresses may have no significant effect on the quality or performance of the assembly. However, in the application described in the following example, the stresses of riveting resulted in excessive warpage during brazing, which led to the adoption of staking.

Example 555. Change From Riveting to Square Staking To Eliminate Warpage During Brazing (Fig. 18)

When the multiple-cam assembly shown in Fig. 18 was assembled by riveting, high radial stresses were set up in joint areas between the hub and the four cams. When these stresses were thermally relieved during the brazing cycle, the resulting warpage altered the radial positioning of the cams beyond specified limits. To eliminate warpage, staking was substituted for riveting as the method of assembly.

The cams were made of cold rolled 1010 steel and were selectively carburized to produce a case 0.020 in. deep on the working edges. They were copper plated (0.0002 in. thick) before brazing to protect the carburized surfaces. The hubs and spacers were made of 1215 steel. All components were vapor degreased before assembly.

Diametral clearance for brazing was 0.0000 to 0.0015 in., and two forms of copper filler metal were used. Preformed rings of 0.018-in.-diam copper wire were placed at joints above three of the cams, and two ⅛-in.-diam daubs of copper powder paste were placed 180° apart at the periphery of the hub, as shown in Fig. 18.

The assemblies were brazed at 2070 F in a 100-kw, mesh-belt conveyor furnace (12-in.-wide belt), in an endothermic atmosphere with a carbon potential of 0.30 to 0.40%. Heating time was 10 min, and production rate was 500 assemblies per hour.

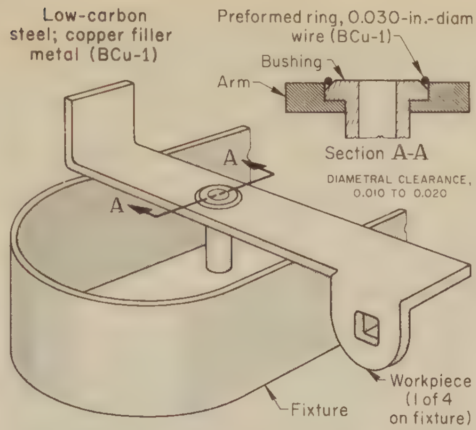

Fig. 19. Arm-and-bushing assembly in position on a simple steel-strap fixture, ready for furnace brazing

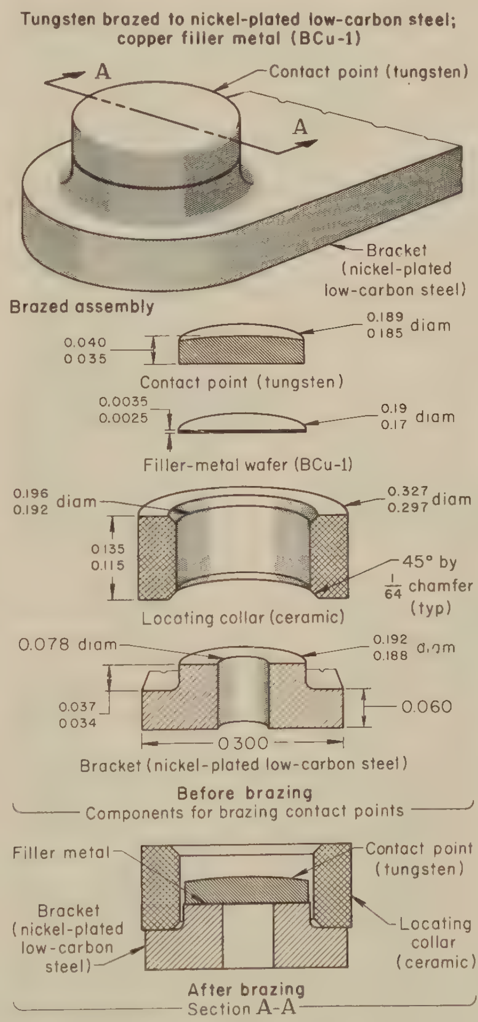

Fig. 20. Distributor-point assembly for which collar used for locating components during brazing was made of ceramic for resistance to wetting by filler metal (Example 556)

Auxiliary Fixtures. In assembling some components for furnace brazing, self-jigging may not be feasible or the assembly may require additional positioning or support that cannot be provided by self-jigging alone, and so the use of auxiliary fixtures is unavoidable. These fixtures can take the form of a simple bracket or wire stand, machined graphite blocks, clamps, or cast supports.

An example of an extremely simple fixture for supporting arm-and-bushing assemblies is shown in Fig. 19. The fixture, a steel strap bent to a U-shape, supported four assemblies in the preferred position for brazing. It provided clearance for the lugs at the end of the arms, and supported the bushing in the vertical position (see Fig. 19) so that the copper filler metal would flow downward into the joint. These assemblies, made of low-carbon steel, were brazed in a conveyor furnace with a 12-in.-wide mesh belt and an exothermic atmosphere.

Low-carbon steel is commonly used for fixtures for short runs; it has the advantage of low cost and the disadvantage of low strength at brazing temperatures. For long production runs, stainless steel and wrought and cast heat-resisting alloys are used.

Fixture design should adhere to the following principles:

1 Sections of fixtures should be as thin as possible, consistent with required rigidity and durability.
2 Fixtures should be designed for minimum contact with the assembly. Point or line contact is preferable to overall surface contact.
3 In general, external fixtures should expand faster, and internal fixtures slower, than the assembly; in applications where tight clamping is required, the reverse is true.
4 To equalize pressure on the assembly from shrinkage during cooling, systems of levers, cams and weights can be used. Wedges and weights often provide good follow-up.

Fixtures are closed or clamped by driving wedges into slots and lugs. The wedges can be easily removed after the assembly is brazed. Spring clamps are seldom used because they undergo relaxation at the brazing temperatures. However, spring clamps made of Inconel, which do not relax as much as those made of carbon steel, are sometimes used. Threaded fasteners should be avoided; if used, they should be made to loose fits, and may be coated with a magnesium hydroxide and alcohol mixture to prevent sticking.

Wetting of Fixtures. Even with a minimum number of contact points between the fixture and the components to be brazed, it is sometimes difficult to prevent the fixture from being wetted by filler metal and sticking or being brazed to the assembly. If the contact surface between fixture and components must be extensive, as in the application described in the following example, selection of a fixture material that resists wetting becomes critical.

Example 556. Selection of Fixture Material for Nonwetting Properties (Fig. 20)

In the assembly shown in Fig. 20 (a distributor-point assembly consisting of a nickel-plated low-carbon steel bracket and a tungsten contact point), a special locating collar was needed for properly positioning a wafer of copper filler metal (BCu-1) and the tungsten contact point with respect to the raised boss on the bracket.

Initially, collars made of steatite (magnesium silicate) were selected, but frequently

these collars were wetted by the copper filler metal and became bonded to the assembly. This necessitated 100% inspection of the finished assemblies and removal of the attached collars. In addition, many collars had to be scrapped after removal.

Several other nonmetallic materials were tried, including a denser steatite, a barium-containing ceramic, a special glass that is resistant to thermal shock, and a lithium-aluminum silicate type of ceramic. Only the special glass and the lithium-aluminum silicate ceramic exhibited satisfactory wetting resistance; the silicate material was finally selected because it was less brittle, could withstand repeated handling, and was less expensive. The change in collar material resulted in a considerable saving in inspection and processing labor and in collar-material costs.

The sequence of operations in assembling and brazing the components was:

1. Seventeen of the contact brackets were placed on a stainless steel furnace-tray fixture.
2. The fixture was placed under a mechanized collar-feeding device, which automatically dropped 17 ceramic collars over the raised bosses on the brackets.
3. The fixture was placed under a feeding device that, by means of vacuum, picked up and deposited 17 filler-metal wafers in position over the bracket bosses.
4. Tungsten contact points were manually set in place within the ceramic collars above the copper wafers.
5. Fixture trays were placed on a 12-in.-wide mesh belt entering a 71-kw electric conveyor furnace at a speed of 8 in. per minute.
6. Assemblies were brazed at 2050 F in an endothermic atmosphere containing 40% hydrogen, 40% nitrogen, and 20% carbon monoxide (dew point, +65 F).
7. After cooling under a protective atmosphere, assemblies were unloaded at the opposite end of the furnace. Heating time was 6 min, and time in the cooling chamber was 30 min.

The furnace was capable of brazing 3400 assemblies per hour, but the number actually brazed depended on the number of operators available for preparing the assemblies. Average production per hour was about 1200 assemblies.

Complex Fixturing. Although simplicity in jigging and fixturing for furnace brazing is highly desirable, complex fixturing is sometimes unavoidable. The following example describes the use of a specially designed fixture for copper brazing of propeller-blade components to aircraft quality standards.

Example 557. Copper Brazing Propeller-Blade Components in a Complex Special Fixture (Fig. 21)

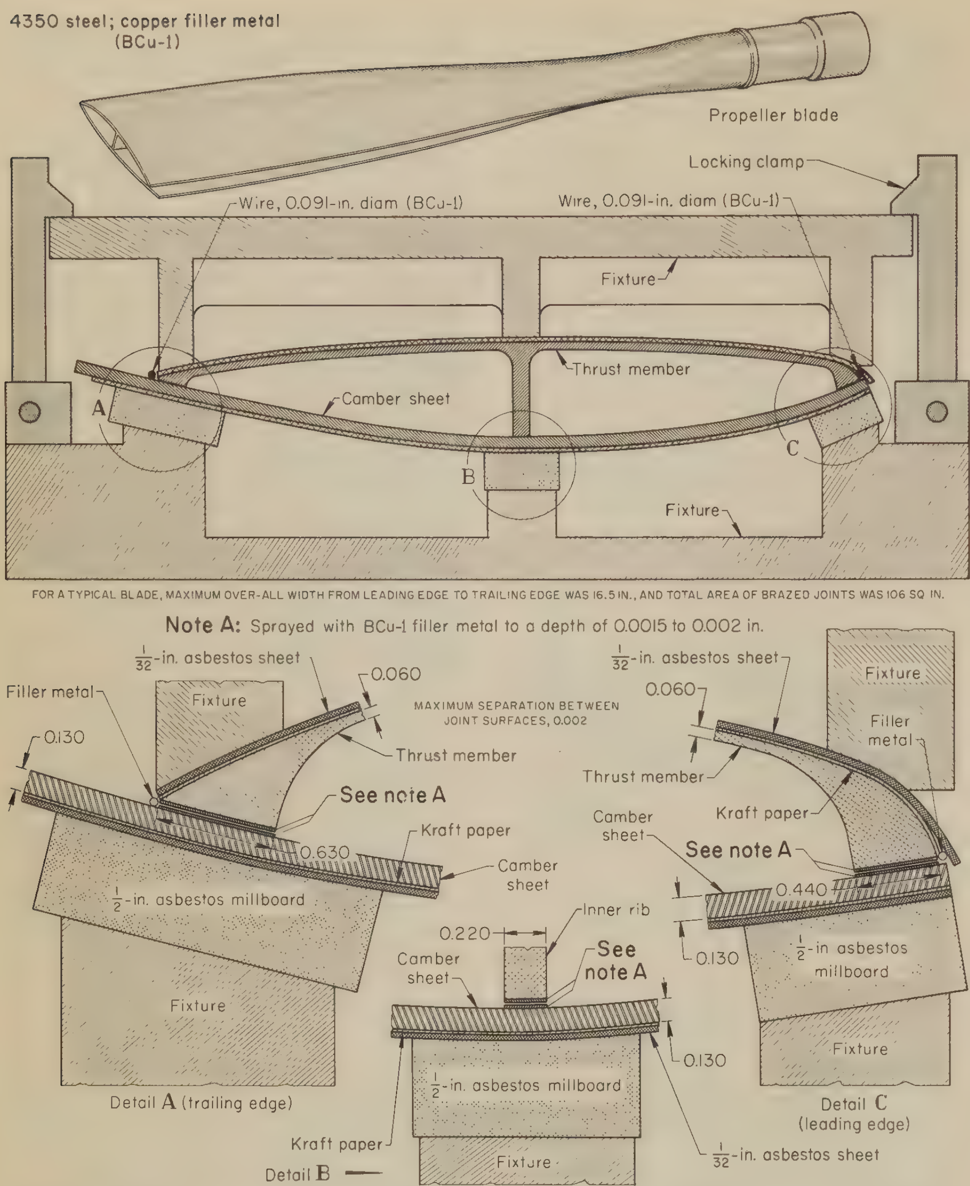

Fig. 21. Propeller blade, and cross section of blade and specially designed fixture for furnace brazing (Example 557)

Two components of a propeller blade — a thrust member and a camber sheet — were successfully brazed to aircraft quality standards, using a complex special fixture that provided accurate contact of the brazed joint surfaces over the variable cross section and contour of the blade length from hub end to tip end. A typical cross section of the blade components in the fixture is shown in Fig. 21. Both the thrust member, which was contour machined from a forging, and the camber sheet, which was cold formed in a die and then die formed and sized at 1000 F, were made of aircraft-quality 4350 steel.

After machining operations were completed, the brazing joint surfaces of the thrust member were hand filed to match the contour of a template. Final checking for fit was done by placing a sheet of carbon paper between the components and clamping them together in the brazing fixture with 29 to 30 tons of force. After the components were removed from the fixture, high spots on joint surfaces, indicated by marks from the carbon paper, were hand filed. By this procedure, separation of joint surfaces was held to a maximum of 0.002 in. Index marks were made on both components to ensure accurate realignment during final assembly.

The joint surfaces were grit blasted, degreased, and dried with an air blast. From then on, the components were handled with clean, dry gloves.

The copper filler metal was deposited by spraying the joint surfaces in the following manner. A template was clamped to the thrust member, and another to the camber sheet. These templates masked off all except the joint area. A predetermined length of precleaned 0.091-in.-diam BCu-1 filler-metal wire was used to spray a copper coating 0.0015 to 0.0020 in. thick on the exposed surfaces.

After spraying, a proprietary high-temperature brazing flux that is active in the range from 1600 to 2000 F was diluted with eight parts of distilled water and sprayed in a thin coat over the joint surfaces of both members. The flux was used to ensure good flow of filler metal in the event of deterioration of the atmosphere in any part of the large brazing furnace.

Before brazing, from one-third to one-half the length of the leading edge of the blade, beginning at the tip, was resistance seam welded, to protect this edge from damage in service caused by impact with another object. If brazing was not to be performed within 8 hr after welding, the blade was placed in a plastic bag to keep it clean.

For brazing, the assembly was placed in the fixture as shown in Fig. 21. Asbestos millboard and sheet distributed the pressure of the fixture (made of 25Ni-20Cr cast heat-resistant alloy) uniformly over the components so that the 19-to-20-ton clamping force that was applied was transmitted evenly to the joints. Kraft paper placed between the asbestos sheet and the assembly facilitated handling and burned to form an ash during the brazing cycle. The ash kept the asbestos from sticking to the blade surfaces. Carefully measured lengths of 0.091-in.-diam BCu-1 copper wire were placed at predetermined intervals along the trailing edge and the nonwelded portion of the leading edge to supply filler metal for internal and external fillets.

Immediately before brazing, a cap was placed over the hub end of the blade, and the blade was purged with dry nitrogen for 5 min before entering the furnace. The fixtured blade was brazed in a special circular furnace, 40 ft in diameter, with nine heating and cooling zones (three preheating zones up to 1850 F, a brazing zone at 2080 F, and five cooling zones in which to lower blade temperature to 300 F before removal). The blade remained in each of the zones for 50 min under protection of a prepared nitrogen-base atmosphere containing

10 to 12% carbon monoxide and 10 to 14% hydrogen; dew point was −15 F in the preheating zones, −9 F in the brazing zone, and −6 F in the cooling zones.

The brazed assembly was removed from the brazing fixture and placed in a horizontal box-type hardening furnace. It was quenched in contour quenching dies with the internal cavity pressurized with nitrogen to ensure contact of the camber-sheet surfaces with the die. The blade was tempered in the same die to a final hardness of Rockwell C 30 to 36.

The quality of the brazed joints was evaluated by radiographic inspection, pressure testing at an internal pressure of 90 to 100 psi, and ultrasonic inspection by the immersion technique. Voids in excess of a very small percentage of the total joint area were cause for rejection. Some rejected blades could be rebrazed, but if the rebrazing was unsuccessful, the entire camber sheet had to be replaced.

After the joint quality was approved, internal fillets adjacent to the joint between the camber sheet and the inner rib of the thrust member were shot peened, for improved fatigue properties, with a snorkel-type tube and nozzle inserted through the hub end of the blade.

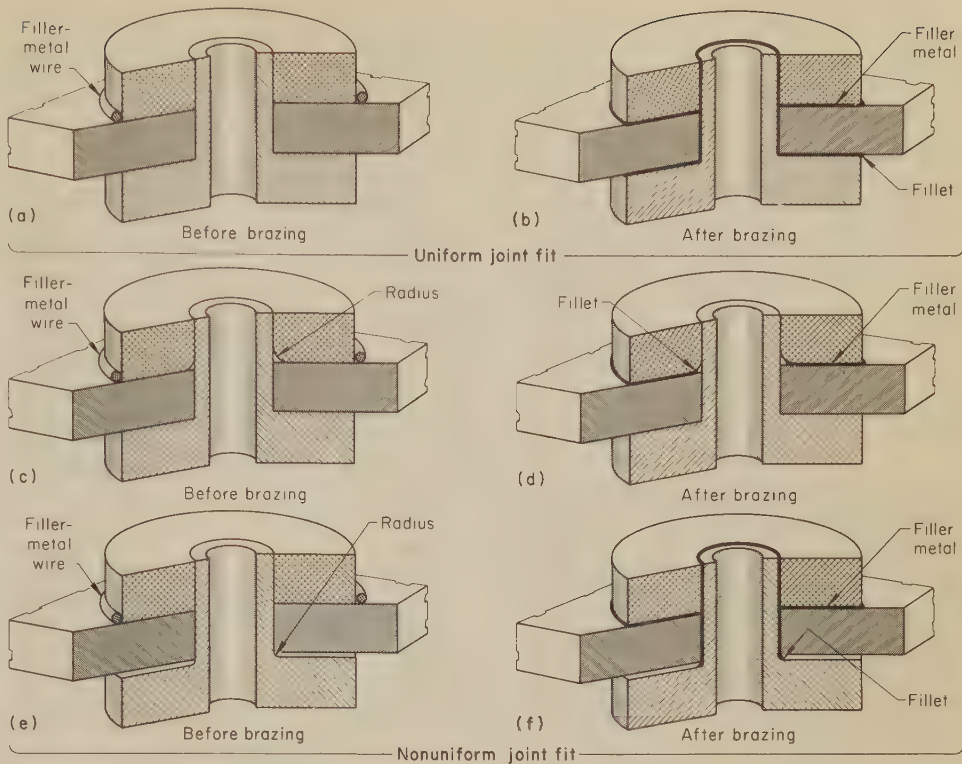
Joint Fit and Design

In brazing, the molten filler metal is drawn by capillary action between closely adjacent, substantially symmetrical surfaces. The distance the filler metal will flow through a joint depends on the clearance between the mating surfaces and on the filler metal used. Molten copper will flow freely and for greater distances than other filler metals in joints with "size-to-size" fit (zero clearance) or an interference fit (negative clearance). The distance of flow of copper increases as joint interference increases, up to the point where the seizing and galling of mating surfaces interferes with capillarity. Conversely, as joint clearance, or gap, is increased, a clearance is reached at which filler-metal flow stops completely. Uniform fit throughout the joint is important, because nonuniform fit will result in nonuniform strength.

Gap Principle. When joint fit is nonuniform, the areas of maximum clearance constitute gaps that interfere with capillary action and impede the flow of filler metal. The effects of uniform joint fit, and of fits containing gaps, on filler-metal flow are shown in Fig. 22. Figure 22(a) shows a joint designed with uniform fit throughout the joint, including the fit at the square internal and external corners. As shown in Fig. 22(b), filler metal from an externally placed wire ring flows uniformly to all parts of the joint, providing a good bond. The joint shown in Fig. 22(c) has uniform fit except at a rounded internal corner. As shown in Fig. 22(d), the gap created by the rounded corner prevents the filler metal from flowing any farther. The joint in Fig. 22(e) has nonuniform fit. The rounded corner and the loose fit at the bottom cause a snug fit at the top. Filler metal flows to most parts of the joint but is blocked at the rounded internal corner (Fig. 22f). The result is an incomplete braze.

The same general principle applies to the design of a joint between a cap and a shell. A joint with uniform fit, as shown in the top view of Fig. 23, results in a uniform bond throughout the joint, whereas a joint with nonuniform fit (or "line contact"), as shown in the bottom view of Fig. 23, results in an incomplete bond and unreliable strength and tightness.

Joint Fit. The amount of clearance or interference provided in a brazed joint directly affects the strength of the joint, although other factors, such as cleanness of the joint, length of the joint, composition of base and filler metals, time at brazing temperature, and subsequent heat treatment, if any, also affect strength. When low-carbon steel components are joined by a copper filler metal, the strength of the joint almost always exceeds the strength of the copper filler metal and, under favorable conditions, is almost equal to the strength of the steel base metal. The effect of fit on joint shear strength is shown by Fig. 24. These data illustrate the desirability of joint fits ranging from zero clearance to in-



Uniform joint fit (a and b) provides a uniform bond throughout the joint. Nonuniform fit, which results in gaps (c, d, e and f), interrupts capillarity and results in incomplete brazing.

Fig. 22. Effects of uniform and nonuniform joint fit on the flow of filler metal in brazing

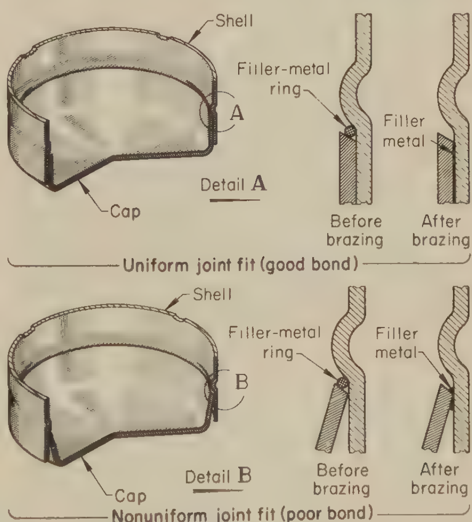


Fig. 23. Effect of joint fit on the bonding of a cap to a shell

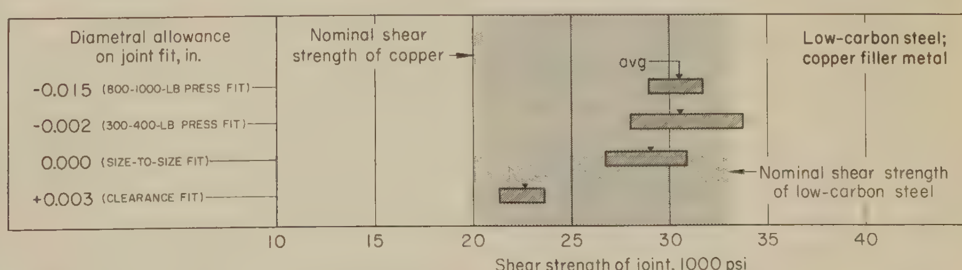
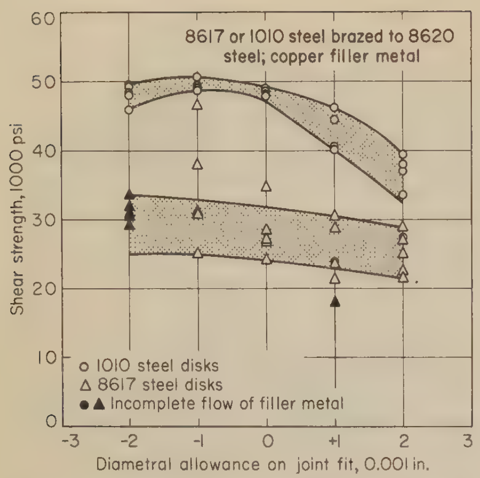


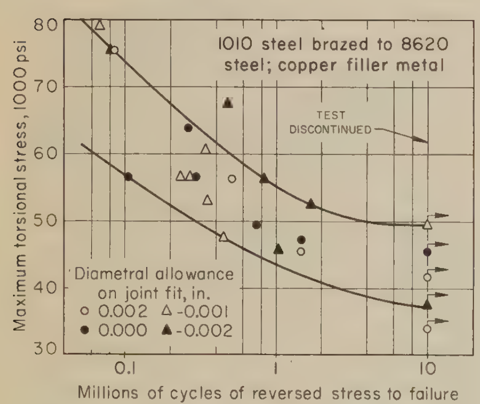
Data are for copper brazed joints in "pull-out" samples made of low-carbon steel. Each sample consisted of a 9⁄32-in.-diam rod copper brazed to a washer 5⁄32 in. thick. After furnace brazing for 20 min, the copper fillets were removed by machining to ensure the accuracy of test results. Ten specimens were prepared for each of the four different degrees of joint tightness. Only six of the ten specimens with the 0.003-in. clearance were tested, because the others exhibited incomplete filling in the joint. (SOURCE OF DATA: George Oswald and Walter Homan)

Fig. 24. Shear strength of copper brazed joints in low-carbon steel as a function of joint fit



Data were taken from tests on parts consisting of an 8620 steel shaft and either an 8617 or 1010 steel disk. Shafts were 9/32 in. in diameter and 4 in. long and were machined to obtain the joint fits shown. Disks were about 2 in. in diameter and 1/4 in. thick with a 0.2500 ± 0.0001-in. center hole. All parts were brazed in an endothermic-exothermic atmosphere, gas carburized at 1500 F for 1 hr, oil quenched, and tempered at 250 F. (SOURCE: William D. Kehr, *Metal Progress*, Jan 1966)

Fig. 25. Shear strength of copper brazed joints between steel components, as a function of joint fit and the composition of the steel



These data, which are the results of tests on brazed joints between 8620 steel shafts and 1010 steel disks, as described with Fig. 25, show that joint fit has essentially no effect on torsional fatigue strength for the range of fits tested. (SOURCE: Same as for Fig. 25)

Fig. 26. Fatigue strength of copper brazed joints as a function of joint fit

terference, although even the joint with 0.003-in. diametral clearance exhibits a strength exceeding the average shear strength of copper. Figure 24 also shows that joints with extreme interference fits are only slightly stronger than joints prepared to a size-to-size fit. Copper filler metal will usually flow through tight fits, provided the brazing temperature and time at temperature are adequate.

For most applications, the recommended diametral fit for copper brazing of low-carbon steel is 0.000 to 0.003-in. interference. High-carbon steels require a slightly looser diametral fit, usually 0.001-in. clearance to 0.002-in. interference. Numerous examples in this article demonstrate the satisfactory use of interference fits and of tight fits approaching zero clearance, but the usefulness of interference fits is limited to assemblies in which the mating surfaces can expand or contract, as required, when pressed together. When the expansion or contraction approaches zero, as is usual with massive components, an interference fit may result in seizing and galling, making it difficult or impossible for copper to flow through the joint.

When maximum joint shear strength is required in brazed assemblies involving low-carbon carbon steels or low-carbon low-alloy steels, one manufacturer of business machines specifies the following diametral allowances on joints between hole walls and tenons to be furnace brazed, using a copper filler metal (wire, foil or paste), and using an endothermic-exothermic gas mixture (71% nitrogen, 15% carbon monoxide, 12% hydrogen, and 2% carbon dioxide, by volume) or dissociated ammonia:

Diameter, in. Hole (+0.0010, —0.0000 in.)	Diameter, in. Tenon (+0.0000, —0.0015 in.)	Diametral allowance on joint fit, in.(a)
0.0625	0.0635	—0.0010 to +0.0015
0.1250	0.1265	—0.0015 to +0.0010
0.2500	0.2520	—0.0020 to +0.0005
0.5000	0.5025	—0.0025 to 0.0000
1.0000	1.0030	—0.0030 to —0.0005
2.0000	2.0030	—0.0030 to —0.0005

(a) Negative allowance is an interference fit; positive allowance is a clearance fit; zero allowance is a size-to-size fit.

These fits were selected after analysis of strength-test data for various nominal joint diameters. For example, Fig. 25 shows the results of shear-strength tests conducted on specimens of the same length with a nominal joint diameter of 0.2500 in. The strongest specimens (1010 steel disks) were those having 0.002, 0.001, or 0.000-in. diametral interference fit. For convenience, the same joint fits were specified for critical assemblies that were subject to alternating torsional loading (torsional fatigue), but test results like those shown in Fig. 26 showed that torsional fatigue strength was essentially independent of joint fit, at least for the range of fits studied.

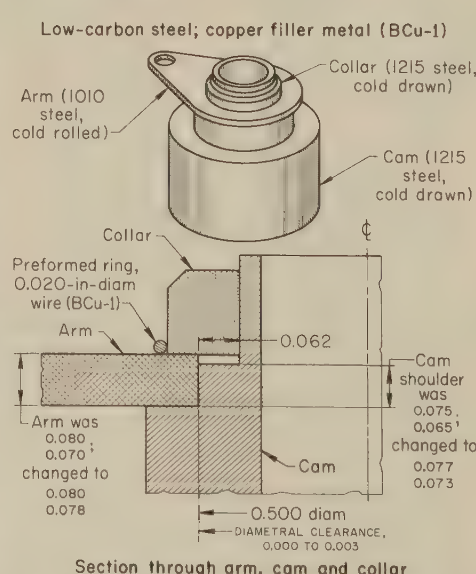


Fig. 27. Assembly for which tolerances on arm stock and cam shoulder were tightened to reduce excessive clearance that prevented adequate flow of brazing filler metal (Example 558)

Low-carbon steels 1010, 8617 and 8620 were used for these tests because they were easier to machine and form than medium-carbon or high-carbon steels and because they were suitable for carburizing after brazing. It was determined that one of the components tested should be a plain carbon steel. As shown in Fig. 25, the specimens with 1010 steel disks had shear strengths as much as 40% greater than those with 8617 steel disks. The reason for this difference was evident when the microstructure of the joints was examined. The joint using 1010 steel disks showed a much deeper penetration of copper on the 1010 steel side of the joint than on the 8620 steel side of the joint. The presence of a chromium-containing oxide film, resulting from incomplete reduction by the furnace atmosphere, probably restricted the diffusion of copper into the 8620 steel. When both components were made of a low-alloy steel, both sides of the joint were affected.

Excessive Joint Clearance. The adverse effect that excessive joint clearance has on the flow of filler metal and the steps taken to correct the difficulty in one application are described in the next example.

Example 558. Tightening of Joint To Reduce Excessive Clearance That Prevented Adequate Flow of Filler Metal (Fig. 27)

Figure 27 shows an assembly in which an arm stamped from cold rolled 1010 steel sheet 0.070/0.080 in. thick (standard tolerance) nested on a 0.065/0.075-in.-high shoulder of a 1215 steel cam. This assembly presented a problem often encountered in brazing assemblies where one component is stamped from steel sheet as-received from the mill — namely, that the thickness of the sheet can vary enough to have an adverse effect on joint clearance. In this assembly, as the thickness of the arm approached the upper allowable limit (0.080 in.) and as the height of the adjacent cam shoulder approached the lower allowable limit (0.065 in.), an annular gap was created beneath the 1215 steel collar that was the third component of the assembly. Under the least favorable conditions, the height of the gap could be 0.015 in., as shown in the sectional view in Fig. 27; the width of the gap was 0.062 in. The copper filler metal, supplied by a 0.020-in.-diam BCu-1 wire, would not flow across and fill a gap of this size; incomplete filling resulted in a joint of unsatisfactory quality.

When the gap was discovered metallographically by sectioning brazed assemblies, it was apparent that tightening of the joint was mandatory. To control the thickness of the arm, tolerances on as-received sheet thickness were changed from standard to select (thickness, 0.078/0.080 in.). The narrowing of tolerances on the cam-shoulder height, to 0.073/0.077 in. (see Fig. 27), also reflected a slight increase in that height. With the maximum possible height of the gap thus reduced, the filler metal could flow past the gap area, down the vertical joint between the cam and the arm, and through the horizontal joint between them. The cam-arm joint was the principal load-carrying joint.

The three components were vapor degreased before assembly and were brazed at 2070 F for 12 min in a 100-kw, mesh-belt (12-in. wide) conveyor furnace in an endothermic atmosphere. Production rate was 250 assemblies per hour. The brazed assemblies were subsequently carburized.

Brazed assemblies rejected for inadequate joint penetration were salvaged by inverting the assembly, placing a filler-metal ring along the outside corner of the joint between the arm and the cam, and rebrazing to fill the cam-arm joint with the ad-

ditional filler metal. Unassembled components with the old tolerances were salvaged by assembling the components with a ring of filler metal in the gap area in addition to the ring at the arm-collar joint, thereby using two sources of copper filler metal in the brazing operation.

Factors Affecting Fillet Size. Provided the volume of filler metal is controlled, joint clearance or interference can, within limits, serve to control the size of fillets. With a fixed volume of filler metal available to the joint, an increase in joint clearance will decrease top-fillet size and increase bottom-fillet size, and a decrease in joint clearance will have the opposite effect. Also, when joint clearance or interference is fixed, an increase or decrease in the volume of filler metal will have a similar effect on fillet size.

With brazed joints, fillet size should be called out on drawing notes only if it is significant to the function of the brazement — large fillets do not necessarily increase joint strength.

The next two examples describe applications involving control of fillet size.

Examples 559 and 560. Controlling the Size of Brazed Fillets

Example 559 — Arm-Hub-Stud Assembly (Fig. 28). In copper brazing the assembly shown in Fig. 28, service requirements made it mandatory to limit the size of the fillet of filler metal at the top of the joint between the stud and the arm to a maximum fillet leg of 0.015 in Diametral clearance between the stud and arm was 0.000 to 0.002 in. It was determined that filler metal in the form of a preformed ring of 0.015-in.-diam copper wire (BCu-1) provided enough filler metal to fill the joint, without exceeding the fillet-size limitation.

Fillet size was not critical at the joint between hub and arm, and an interference fit of 0.0005 to 0.0030 in. and a 0.018-in.-diam filler-metal wire were selected.

As indicated in Fig. 28, the hub and stud were made of 1215 steel, and the arm was made of 1010 steel. The components were degreased before assembly and were brazed at 2070 F in a 100-kw, mesh-belt conveyor furnace (12-in.-wide belt). Heating time at 2070 F was 9 min, and production rate was 1750 assemblies per hour. An endothermic atmosphere was used in the furnace.

Example 560 — Shaft-and-Plate Assembly (Fig. 29). The fillet of filler metal at the top junction of the shaft and the plate of the assembly shown in Fig. 29 was required not to exceed 0.010 in. when measured with a ring gage after nickel plating (0.0003 in. thick). The shaft, made of leaded low-carbon steel, and the low-carbon steel plate were vapor degreased before they were assembled and were held by riveting, as shown in Fig. 29. Diametral clearance between components was held between 0.001 and 0.005 in. The filler metal was in the form of a preformed ring made of 0.013-in.-diam copper wire (BCu-1), and was preplaced at the joint, as shown in Fig. 29. This volume of filler metal was enough to completely fill the joint without forming fillets larger than allowed.

The assembly was brazed in an electric pusher-type furnace at 2050 F, in a nitrogen-base atmosphere (30% CO and 16% H_2). Brazing time was 15 min, and production rate was 150 assemblies per hour.

Notched Joint for Venting. Although joints with interference fits are common with copper brazing because of the exceptional flow characteristics of copper, flow into blind passages may sometimes be hindered by entrapped air. Venting of a joint with interference fit can promote normal flow, as in the following example.

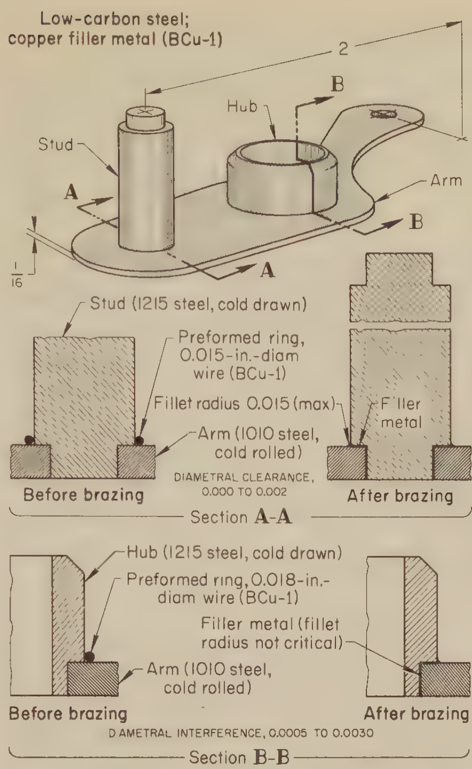

Fig. 28. Assembly for which size of filler-metal fillet in one of two brazed joints was controlled by use of smaller-diameter wire, and by designing joint with clearance instead of interference (Example 559)

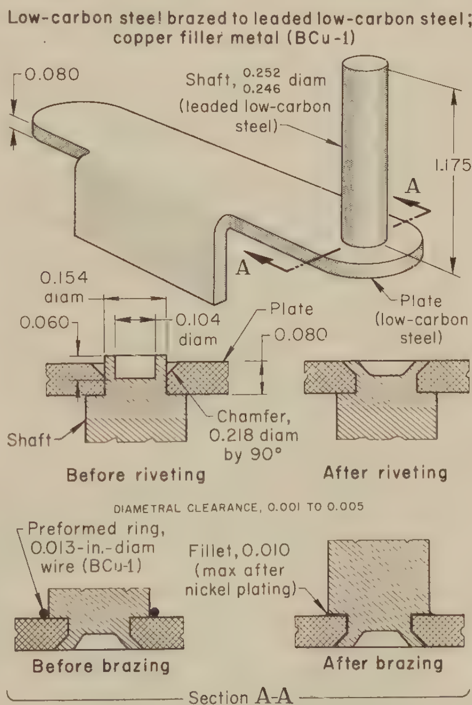

Fig. 29. Brazed riveted assembly for which size of filler-metal fillet was controlled by use of a preformed ring of filler wire of proper diameter (Example 560)

Example 561. Venting an Interference-Fit Joint To Promote Flow of Filler Metal (Fig. 30)

When sectioned samples of the brazed multiple-gear assembly shown in Fig. 30 revealed incomplete penetration of the joints, it was determined that the cause was air entrapped in the joint and that the original joint design (section A-A in Fig. 30) required modification in the form of venting. Venting was achieved by notching the internal diameters of the gears at two locations, 180° apart (see section B-B in Fig. 30), in a blanking die. Without a change in joint fit (0.0005 to 0.0030-in. diametral interference), which was required in order to maintain concentricity, or the location of the filler-metal preforms (rings of 0.015-in.-diam BCu-1 copper wire), venting sufficed to relieve entrapped air, thereby allowing unhindered flow of filler metal to fill the joints. Joint filling was known to be complete when copper was visible at the side of the joint opposite that where the filler-metal ring was placed.

The components, of low-carbon steel, were vapor degreased before assembly and were brazed in a 100-kw, mesh-belt conveyor furnace (12-in.-wide belt) at 2070 F, in an endothermic atmosphere. Brazing time was 10 min, and production rate was 3500 assemblies per hour.

Joint Design. In general, lap joints are preferred for brazing. These joints depend for their strength on penetration between close, conforming surfaces, rather than on external fillets; the joints are usually intended to be stressed in shear. A rule of thumb is to make the length of the joint at least three times the thickness of the thinnest section.

Joints should be designed especially for brazing. Six joint designs commonly used for arc welding are compared with their counterparts for brazing in Fig. 31. Any of the joints shown for arc welding could be joined by brazing, but at great sacrifice in strength. Actually, each of the joint designs shown in Fig. 31 as being used for brazing is a lap joint.

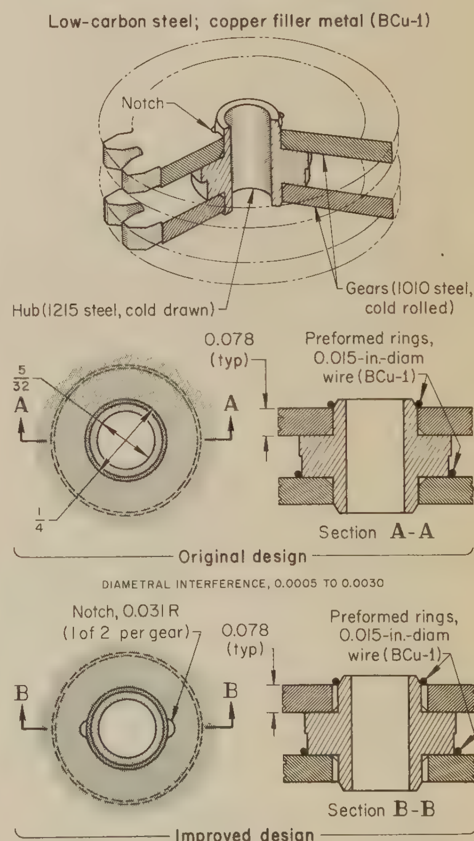

Fig. 30. Multiple-gear assembly to which notches were added to vent the joint and allow complete flow of brazing filler metal through the joint (Example 561)

Table 5. Compositions, Solidus and Liquidus Temperatures, and Brazing-Temperature Ranges of Silver Alloy Filler Metals Used in Furnace Brazing (AWS A5.8)

AWS classification	Composition, % Ag	Cu	Zn	Cd	Ni	Temperature, F Solidus	Liquidus	Brazing
BAg-1	44 to 46	14 to 16	14 to 18	23 to 25	....	1125	1145	1145 to 1400
BAg-1a	49 to 51	14.5 to 16.5	14.5 to 18.5	17 to 19	....	1160	1175	1175 to 1400
BAg-3	49 to 51	14.5 to 16.5	13.5 to 17.5	15 to 17	2.5 to 3.5	1170	1270	1270 to 1500
BAg-4	39 to 41	29 to 31	26 to 30	....	1.5 to 2.5	1240	1435	1435 to 1650
BAg-5	44 to 46	29 to 31	23 to 27	....	....	1250	1370	1370 to 1550

In designing for brazing, butt joints are generally avoided. If the use of a butt joint is unavoidable, the entire assembly must be designed to ensure that there will be no deflection or bending stresses at the brazed joint. Concentration of bending stresses at the joint will cause the brazed filler metal to tear, especially if the base metal has a higher modulus of elasticity than the filler metal. In brazing steel with a copper filler metal, the difference in elastic modulus is pronounced (30 million vs 17 million psi).

Change in Section Thickness. When a brazed assembly is subjected to bending stresses or fatigue, an abrupt change in section thickness in the joint area will promote failure at the joint, just as in a welded joint. This type of failure is caused by the relative flexibility of the thin section and rigidity of the heavy section. Failure can be avoided by tapering the heavy section in the joint area, thereby providing the two components with approximately equal stiffness at the point where failure would otherwise occur. This reduction in section also facilitates brazing, because it provides more uniform heating, uniform clearance, and uniform filler-metal flow.

Surface Condition. The importance of cleaning as a preparatory step before brazing is discussed in the section on Cleaning and Surface Preparation for Brazing. Satisfactory flow of filler metal is highly dependent on the cleanness of the joint area.

Surface finish also affects capillarity. The relatively smooth surfaces that are obtained by polishing or fine grinding are less readily wetted by molten filler metal than are rough surfaces. Therefore, it is sometimes advisable to roughen the mating surfaces, such as by rubbing with 60 to 100-grit silicon carbide papers, to prepare them for brazing. A grit blasted or shot blasted surface is most readily wetted. Sand blasting is not recommended, because embedded sand particles interfere with wetting action. Any surface treatment that involves the use of aluminum oxide or titanium oxide abrasives should be avoided, because these abrasives deposit a surface contaminant a few microns thick on the parts, which generally inhibits wetting.

Brazing With Silver Alloy Filler Metal

Because heat input to the work is localized in torch and induction brazing of steel, the lower melting and brazing temperatures of a silver alloy filler metal are distinctly advantageous; less often are these advantages a significant factor in furnace brazing of steel. Consequently, the use of silver alloy filler metals is generally limited in furnace brazing to applications for which the copper filler metals or the high brazing temperatures (2000 to 2100 F) they require are not suited. Among these applications are the following:

1. Brazing a carbon or low-alloy steel to a stainless steel or to a nonferrous metal or alloy such as copper or brass
2. Brazing with joint clearances that are larger than those permitted in copper brazing
3. Brazing an assembly that will distort excessively or suffer a loss of desirable properties at the temperatures used in copper brazing
4. Brazing subsequent joints in a copper brazed assembly — a practice referred to as step brazing.

Types and Forms of Filler Metal. Five silver alloy filler metals generally used in furnace brazing are identified in Table 5, including chemical compositions, and solidus, liquidus and brazing temperatures.

BAg-1 and BAg-1a filler metals are used in furnace brazing carbon steel to carbon steel, to austenitic stainless steel, and to copper or copper alloys. These filler metals are quaternary silver-base alloys containing copper, zinc and cadmium. They are free-flowing, with a relatively low brazing-temperature range. In furnace brazing, BAg-1a is often preferred to the less costly BAg-1 because of its higher silver and lower cadmium contents, which render it less susceptible to joint porosity.

Silver alloy filler metals that contain substantial percentages of cadmium were originally intended for use in torch or induction brazing, not furnace brazing. There is a large loss of cadmium during furnace brazing and the resulting joint metal will be considerably different in cadmium content than that in a joint brazed by torch or induction. However, the cadmium-bearing filler metals are widely used for furnace brazing.

The same combinations of metals and alloys can be furnace brazed with BAg-5 filler metal as with BAg-1 and BAg-1a filler metals. BAg-5 is a ternary silver-base alloy with a considerably higher brazing-temperature range. It is used in applications where a free-flowing filler metal is not desirable because of joint design or other factors. Because it is cadmium-free, it is used in applications where cadmium is prohibited, as in food-handling and pharmaceutical equipment.

Filler metals BAg-3 and BAg-4 contain nickel, and are used in furnace brazing steel to ferritic or martensitic stainless steels containing chromium as the principal alloying element and little or no nickel. Joints in these steels are susceptible to interface corrosion in water or moist air unless they are brazed without flux, using a nickel-containing filler metal. BAg-4 is used when a wider range between solidus and liquidus is required than that of BAg-3. Both alloys are also used in brazing carbide tips to steel tools.

Fluxes. When filler metals BAg-1, BAg-1a, BAg-3, BAg-4 and BAg-5 are used, a flux is required in furnace

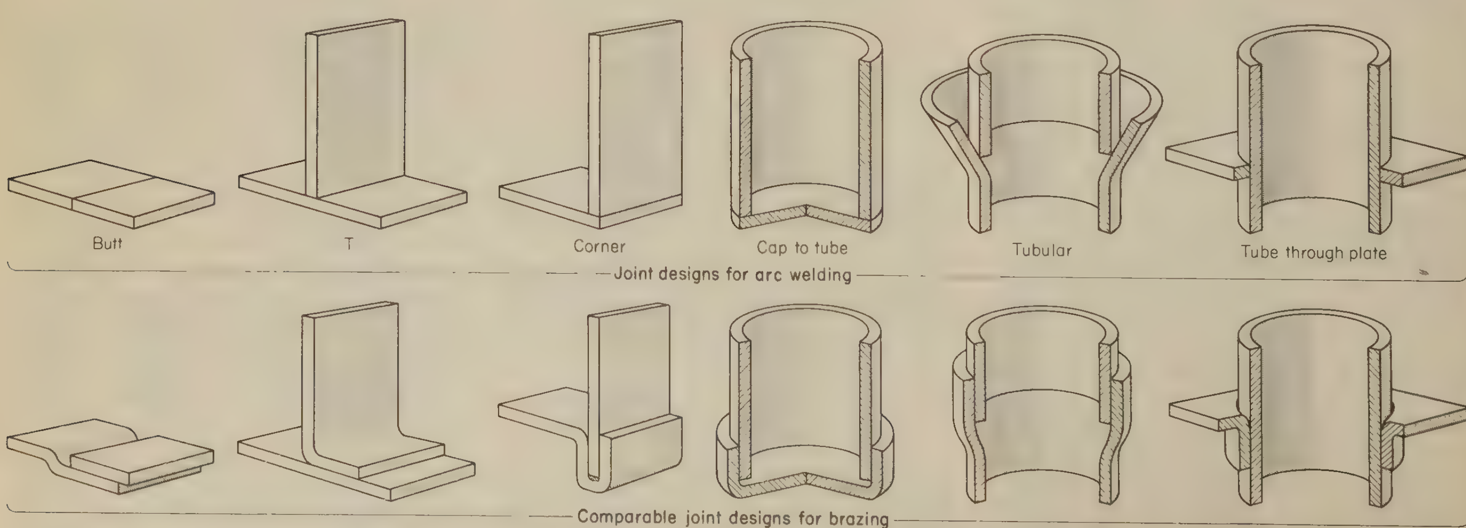

Fig. 31. Comparison of joint designs commonly used in arc welding and comparable designs used in brazing (H. R. Brooker and E. V. Beatson)

brazing steel to steel, or steel to a dissimilar metal. Without corroding the base metals, the flux serves to reduce surface oxides, ensuring that filler metal will flow and that base metals will be satisfactorily wetted by it.

Flux of AWS type 3A satisfies these requirements and is widely used in furnace brazing with silver alloy filler metals. It contains boric acid, borates, fluorides, fluoborate, and a wetting agent; it is effective in furnace brazing — with protective atmosphere — within the temperature range of 1050 to 1600 F. It is available as a paste or powder, and can be mixed with water, alcohol, or monochlorobenzene for thinning to a liquid consistency. Depending on consistency, flux is applied by brushing or spraying, or by metering from a gun.

Flux residues must be completely removed from assemblies after brazing. The fluoride-type fluxes generally used in silver brazing develop residues that are hygroscopic and corrosive. Methods of removing flux residues from base metals are discussed on pages 630 and 631 in the article on Torch Brazing.

Joint Clearance. Recommended diametral joint clearances for brazing with silver alloy filler metals range from 0.002 to 0.005 in. This range takes into account the differences in the flow characteristics and liquidus temperatures of the various silver alloy filler metals. Size-to-size (zero clearance) and interference fits are not recommended, although joints with interference fits have been successfully silver brazed (see Example 562).

Furnaces. The batch-type box furnaces and mesh-belt conveyor furnaces used in copper brazing are generally suitable for brazing with silver alloy filler metals, provided that the furnaces can maintain satisfactory temperature uniformity in the lower ranges.

Because of their chemical activity, brazing fluxes are potentially damaging to furnace components such as heating elements, mesh belts, rolls, hearth plates, and refractories. They temporarily reduce protective oxides, until their activity is exhausted, and then the oxides re-form. The most severe damage occurs when fluxes are permitted to make direct contact with furnace components. It is common practice to equip silver brazing furnaces with alloy muffles to protect furnace components against flux attack, but some plants report that the use of muffles is unnecessary. Assemblies are usually placed on catch trays that collect flux drips throughout the brazing cycle. The damaging effects of flux constituents in volatilized form are apparently modified to a considerable extent by dilution with the protective furnace atmosphere and by diversion to a venting system.

Protective Atmospheres. The protective atmospheres most commonly used in furnace brazing with silver alloy filler metals are rich exothermic gas, endothermic gas, dissociated ammonia, and dry hydrogen. Even when a flux is used, an atmosphere is usually employed, to minimize or prevent oxidation and discoloration of the base metals and to ensure that the flux performs its functions.

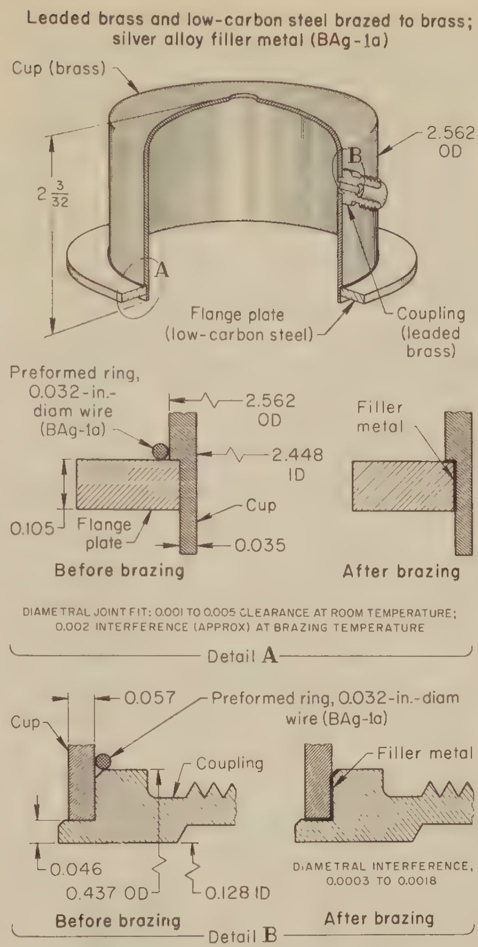

Fig. 32. Brass and steel bellows-housing assembly that was furnace brazed in an endothermic atmosphere, using a silver alloy filler metal and flux (Example 562)

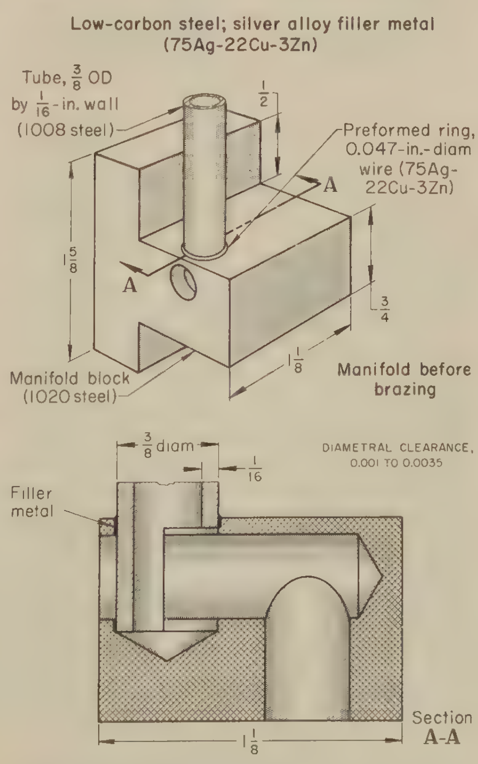

Fig. 33. Manifold assembly that was furnace silver brazed, using a protective atmosphere of dissociated ammonia and no flux (Example 563)

Exothermic and endothermic atmospheres are less expensive than dissociated ammonia or dry hydrogen; they are used in furnace brazing of steel to steel or to oxygen-free copper or copper alloys, using a flux and BAg-1a or BAg-5 filler metal.

Provided dissociation is complete (100%), dissociated ammonia can be used in nearly all furnace brazing applications involving the use of silver alloy filler metals. If dissociation is less than 100%, however, the atmosphere may promote nitrogen pickup (nitriding) in carbon and low-alloy steels.

The use of dry hydrogen as a protective atmosphere is generally limited to fluxless brazing applications in which the most strongly reducing atmosphere available is required to ensure removal of surface oxide and the satisfactory flow of filler metal. The hydrogen must be extremely dry (dew point, −60 F or less) for maximum effectiveness.

Examples of Silver Brazing. The two examples that follow illustrate the use of an endothermic gas and dissociated ammonia as protective atmospheres for furnace brazing, using silver alloy filler metals. The first of these examples also illustrates the use of BAg-1a filler metal with flux, and the second deals with fluxless brazing, using a special ternary silver alloy filler metal.

Example 562. Silver Brazing Steel to Brass in an Endothermic Atmosphere, Using Flux (Fig. 32)

The bellows housing shown in Fig. 32 was brazed at 1350 F in an electric box furnace in an endothermic atmosphere, using BAg-1a silver alloy filler metal and a type 3A flux. The low-melting silver filler metal was selected to avoid damaging the brass parts of the assembly. An endothermic atmosphere was selected because of availability and cost.

As shown in Fig. 32, the housing assembly consisted of a deep drawn brass cup, a leaded brass coupling, and, outside the critical area requiring corrosion resistance, an inexpensive low-carbon steel flange plate. Before assembly, the brass components were bright dipped and the steel plate was vapor degreased. The coupling was press fitted into the side of the cup, and a preformed ring of 0.032-in.-diam BAg-1a wire was snap fitted onto the shoulder of the coupling. Then the brass cup was seated in the hole of the flange plate, and a preformed ring of 0.032-in.-diam BAg-1a wire was snap fitted to the cup. Flux was applied to the joint areas, and assemblies were placed on furnace trays in lots of 30 per tray.

Each trayload was pushed into the hot chamber of the furnace, where it remained, in an endothermic atmosphere, for 10 min. Because the liquidus temperature of the filler metal was 1175 F, the furnace temperature of 1350 F provided a slightly accelerated heating rate. At the end of the heating cycle, the tray was pushed into an adjacent cooling chamber, where the assemblies were again protected by an endothermic atmosphere. For safety, atmosphere in both heating and cooling chambers was maintained at positive pressure, and flame curtains were kept burning at entrance and exit ends of the furnace.

Production rate was 180 assemblies (or 360 brazed joints) per hour. Brazing costs per assembly were as follows:

BAg-1a preform (large)	$0.0430
BAg-1a preform (small)	0.0063
Total filler-metal cost	$0.0493
Assemble and flux (2.12 min)	$0.0795
Brazing labor	0.0139
Total labor cost	$0.0934
Total per assembly	$0.1427

After brazing, the flux residue was removed and brazed assemblies were cleaned by a combination of pickling and bright dipping. (Although the endothermic atmosphere minimized the amount of cleaning required, it did not completely eliminate the need for cleaning.)

Example 563. Brazing of Steel in Dissociated Ammonia, Using a Ternary Silver Alloy Filler Metal and No Flux (Fig. 33)

Figure 33 shows a hydraulic manifold assembly consisting of a 1008 steel tube and a 1020 steel manifold block containing machined passages for the flow of oil. The assembly did not lend itself to interference fits, characteristic of copper brazing, nor could a flux residue be readily cleaned from the blind internal passages. Consequently, diametral joint clearances were established at 0.001 to 0.0035 in., and a ternary silver alloy that did not require flux was selected as the brazing filler metal. This alloy (75% Ag, 22% Cu, 3% Zn), with a liquidus temperature of approximately 1500 F, developed satisfactory wetting characteristics with the reducing potential of a dissociated ammonia atmosphere.

The assemblies were brazed in a mesh-belt conveyor furnace heated to 1600 F, using the silver alloy filler metal in the form of wire rings. The brazing time at 1600 F was 12 min, during which period it was estimated that assemblies were heated to between 1500 and 1550 F. Production rate was 60 assemblies per hour.

Furnace Brazing vs Other Brazing Processes

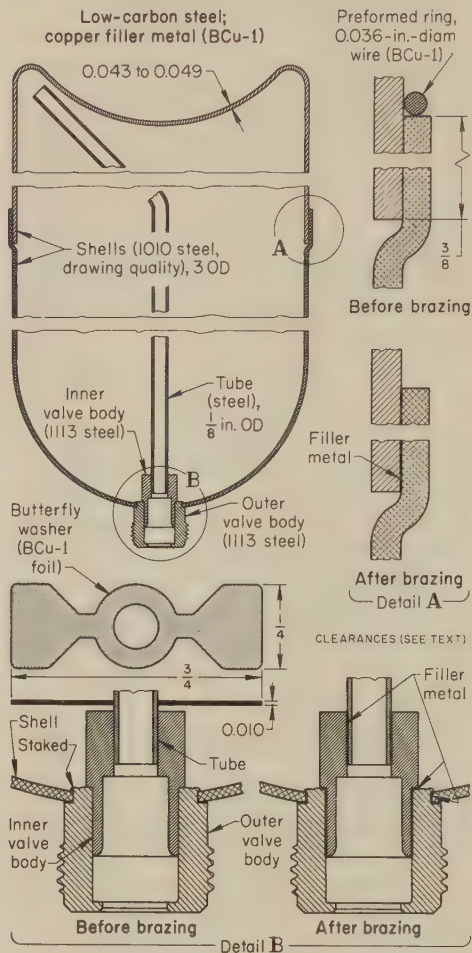
Among the advantages of furnace brazing are the abilities to achieve high production rates, to provide a high degree of reproducibility of results, and to use inexpensive copper filler metals and inexpensive protective atmospheres that generally are not suited to other brazing processes, particularly induction and torch brazing.

The five examples that follow describe production applications in which furnace brazing was selected in preference to, or replaced, induction brazing or torch brazing. In all applications, the adoption of furnace brazing resulted in the substitution of a copper filler metal for a silver alloy filler metal. In one application, the cost of furnace brazing with a silver alloy filler metal was estimated before furnace brazing with a copper filler metal was approved and adopted. In four of the five applications, the atmosphere used for furnace brazing was an exothermic-base gas mixture.

Example 564. Cost Reduction and Product Improvement Resulting From Use of Furnace Copper Brazing Instead of Induction or Furnace Silver Brazing (Fig. 34)

When the steel aerosol-container assembly shown in Fig. 34 was brazed by induction, using BAg-1 silver alloy filler metal and flux, flux residue, which clogged valve and tube passages, was difficult and expensive to remove and, when not removed completely, absorbed moisture and was a potential source of corrosion. Moreover, a large percentage of the induction brazed containers leaked, because on a large production scale, it was difficult to provide the surfaces to be brazed with the degree of cleanness and uniformity of fluxing needed to prevent leaks.

On the basis of an engineering and cost study, it was determined that brazing the assembly in a furnace, in a protective atmosphere, using a copper filler metal (BCu-1) that did not require a flux, would eliminate the passage-clogging and cleaning problems, improve joint quality, increase production rate, and reduce brazing costs. As part of the same study, costs were estimated for furnace brazing using BAg-1 silver alloy filler metal. Actual costs were established for furnace brazing with



Item	Silver brazing (est)	Copper brazing (actual)
Annual Costs per Furnace		
Filler metal	\$180,300(a)	\$ 9,680(b)
Furnace power(c)	4,910	7,420
Atmosphere gas(d)	2,100	2,100
Maintenance	24,335	25,350
Furnace investment	10,500(e)	11,000(f)
Interest(g)	2,110	2,190
Taxes and insurance(h)	2,110	2,190
Labor and overhead(j)	142,000	119,000
Total annual cost per furnace	\$368,365	\$178,930
Total cost per assembly(k)	\$0.1316	\$0.0639
Saving by copper brazing:		
Annual, per furnace		\$189,435
Per assembly		\$0.0677

(a) For BAg-1 wire at \$1.12 per troy ounce, foil at \$1.18 per troy ounce. (The costs are lower than those given on page 600 because of the large quantity used.) (b) For BCu-1 wire at 89¢ per pound, foil at \$1.20 per pound. (c) At 1¢ per kilowatt-hour. (d) Coke-oven gas at 75¢ per 1000 cubic feet. (e) \$84,500 (furnace cost) divided by 8 (years of depreciation). (f) \$88,000 (furnace cost) divided by 8 (years of depreciation). (g) 5% of half of furnace cost. (h) 2½% of furnace cost. (j) At \$8.50 per hour for skilled labor, \$5.70 per hour for semiskilled labor, including overhead. (k) Based on annual production of 2.8 million assemblies per furnace.

Fig. 34. Furnace brazed aerosol container for which copper was used instead of silver alloy as the filler metal, on the basis of the estimated cost saving shown in the table (Example 564)

copper filler metal after the furnace brazing operation was adopted. Both sets of costs are shown in the table that accompanies Fig. 34.

In this cost comparison, furnace costs (investment, interest, and taxes and insurance) and costs for power consumption and maintenance are higher for copper brazing because of the higher brazing temperature, but the estimated maintenance cost for silver brazing is high because of anticipated flux attack on alloy trays, rolls and heating elements. Labor cost for silver brazing is higher because of the need for fluxing and subsequent cleaning. Excluded from the comparison are the costs of forming the rings of filler-metal wire and stamping the butterfly washer from filler-metal foil (which would have been nearly equal for both filler metals), and the costs for flux and for reworking of rejects. The major item in the comparison is cost of the two filler metals, and it is apparent that the use of copper offered a substantial over-all cost saving.

The furnace equipment that replaced induction brazing consisted of two 180-kw electrically heated roller-hearth furnaces, with door openings 30 in. wide by 13 in. high, heating chambers 9 ft long, and cooling chambers 30 ft long. Furnaces were supplied with a rich exothermic atmosphere generated by two 1500-cfh generators from coke-oven gas.

Before being furnace brazed, the 1010 steel shells of the container were washed with hot caustic and rinsed well, and the inner and outer valve bodies, machined from 1113 steel, were vapor degreased. The joint between the shells had diametral interference of 0.002 to 0.010 in., and ⅜-in. overlap. The inner valve body was knurled for a press fit in the outer valve body. The outer body was free fitted into the shell and was staked in four places. The tube was press fitted into the inner valve body and was flattened slightly below a copper butterfly washer, to hold the washer in place. The butterfly washer, which served as filler metal in the valve-body area, was made of 0.010-in.-thick commercially pure copper foil. Filler metal for the joint between the shells was a preformed ring of 0.036-in.-diam commercially pure copper wire.

The brazing cycle consisted of heating for 12 min at 2100 F, and cooling for 40 min. The assemblies were moved through the furnace on trays, each tray containing 54 assemblies. One skilled operator controlled both furnaces, and nine semiskilled workers were required for assembly. Production rate per furnace was 702 assemblies per hour. Power consumption was 157 kwhr per hour per furnace; each atmosphere generator consumed 675 cubic feet of coke-oven gas per hour.

Examples 565, 566 and 567. Change From Manual Torch Brazing to Furnace Brazing To Increase Production (Fig. 35)

When furnace brazing with copper filler metal replaced manual torch brazing with a silver alloy filler metal, production rates for a tube-and-lever assembly (Example 565), a can-opener blade assembly (Example 566), and a plate-and-bushing assembly (Example 567) increased by as much as 500%. As shown in Fig. 35, the components of the tube-and-lever and the can-opener blade assemblies were assembled by staking before furnace brazing. Staking helped to compensate for the large joint clearances, which were designed initially for brazing with silver alloy filler metal. The plate-and-bushing components were assembled by fixturing, the fixture consisting of a steel strap bent to the U-shape shown in Fig. 35. Each fixture supported three or four assemblies.

All three assemblies were brazed at 2000 to 2010 F in a conveyor furnace with a 12-in.-wide mesh belt and an exothermic atmosphere. The filler metal was supplied by preformed rings of BCu-1 copper wire, 0.020 or 0.030 in. in diameter, depending on

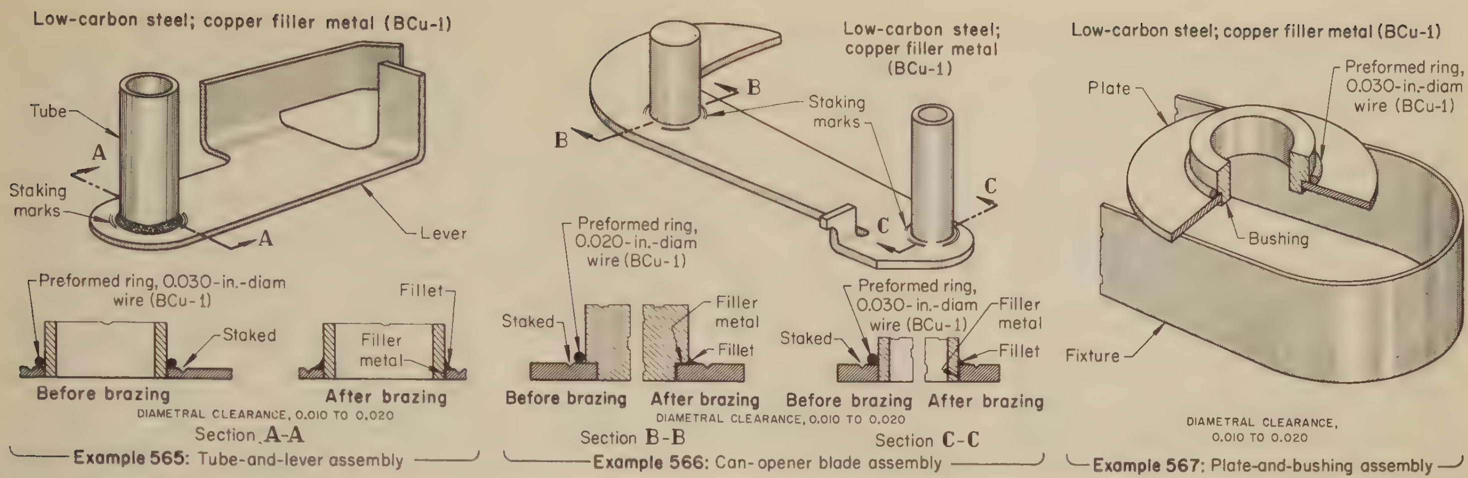


Fig. 35. Three steel assemblies for which furnace brazing was substituted for manual torch brazing (Examples 565, 566 and 567)

joint requirements. Furnace-belt speed was adjusted for each of the three assemblies to ensure full joint penetration and the formation of a brazed fillet.

Example 568. Production-Rate Increase of 128% With Change From Automatic Torch Brazing to Furnace Brazing (Fig. 36)

When the throttle-linkage assembly shown in Fig. 36 was brazed in an automatic, multiflame torch brazing machine, using a silver alloy filler metal, production rate was 240 assemblies per hour. A change to furnace brazing, using a copper filler metal, resulted in a production rate of 548 assemblies per hour — an increase of 128%.

Components were assembled for brazing by placing the 12L14 steel shaft in a nesting fixture and pressing the 1010 steel lever into position over the shaft with an arbor press. For torch brazing, the operator placed a preformed ring of silver alloy filler metal over the shaft after the components were assembled, and applied flux to the joint with a paintbrush. The assembly was then placed in a ceramic fixture on a chain conveyor that carried it past several gas burners that preheated the base metal and melted the filler metal. The brazed assembly was unloaded automatically.

For furnace brazing, a copper filler-metal paste was applied to the joint area by means of an automatic, air-actuated paste dispenser that metered the amount applied. Assemblies were then placed on a stainless steel plate that then was placed on the furnace conveyor belt. Assemblies were brazed at 2100 F in a 71-kw, mesh-belt conveyor furnace (12-in.-wide belt), in an endothermic atmosphere (65 F dew point) prepared from natural gas. Time at brazing temperature was about 10 minutes. The furnace used was a muffle furnace that was equipped with two heating zones and two water-cooled cooling chambers.

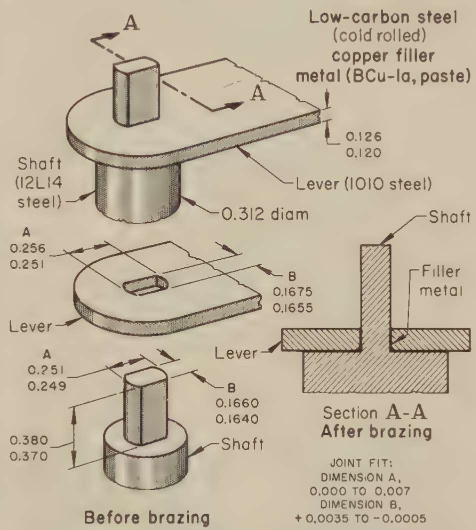

Fig. 36. Throttle-linkage assembly for which furnace brazing was substituted for automatic, multiflame torch brazing to increase production (Example 568)

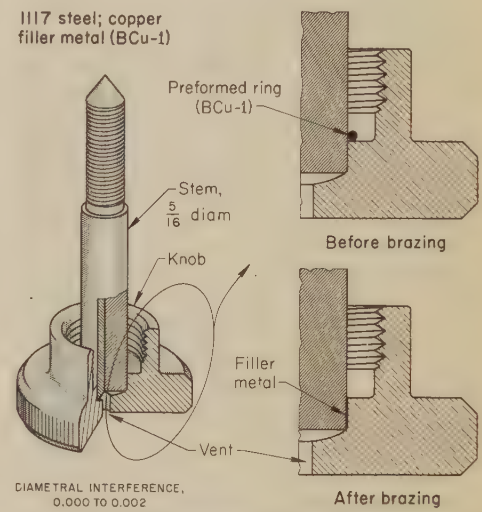

Fig. 37. Shutoff-valve stem that was changed from a one-piece product to a brazed, two-piece, automatic-bar-machine product to save material and machining time (Example 569)

Furnace Brazing To Supplement, Modify or Replace Other Fabricating Processes

From a design standpoint, furnace brazed assemblies are of two general types: (*a*) those designed initially for brazing, and (*b*) those redesigned for brazing for any of several reasons, including product improvement, increased production rate, ease of fabrication, and cost. Nearly all of the examples of practice considered in previous sections of this article have dealt with assemblies that were designed initially for brazing, but many high-production parts have been redesigned to permit the substitution of furnace brazing for other fabricating processes. Examples in which assemblies were redesigned for brazing are considered in this section; each describes a brazing application that was adopted to supplement, modify, or replace another fabricating process.

Machining and Brazing. Furnace brazing can sometimes be used in combination with machining to conserve material and machining time and to simplify the fabrication of complex shapes. Usually, this entails the subdivision of a single, complex part into two or more relatively simple elements that can be assembled and joined by furnace brazing. Applications in which machining and furnace brazing were judiciously combined to simplify complex parts are described in the first two of the three examples that follow. The third example describes the combining of furnace brazing with machining to reduce the fabrication cost of a relatively simple part.

Example 569. Production by Machining and Furnace Brazing That Saved Material and Machining Time (Fig. 37)

Originally, the shutoff-valve stem shown in Fig. 37 was machined in one piece from 1⅛-in.-diam 1117 steel bar stock, 2½ in. long and weighing 11 oz. As made in one piece, the valve stem was too complicated to be completed in an automatic bar machine, so production rate was slow and highly skilled labor was required to complete the part in a secondary machining operation.

When the knob and stem were redesigned as separate components to be joined by furnace brazing, both components were simple enough to be turned in automatic bar machines, reducing machining time and saving 7½ oz of stock, or about two-thirds of the total weight of the original blank.

When made as a separate component, the knob was turned from a 9⁄16-in. length of 1⅛-in.-diam 1117 steel bar stock. The stem was turned from a 2½-in. length of a 5⁄16-in.-diam bar of the same steel. As shown in Fig. 37, the components were machined for a light press fit (0.000 to 0.002 in. interference).

Before assembly, the components were cleaned by immersion in a caustic bath. They were then assembled, and BCu-1 copper filler metal in the form of a wire ring was placed over the stem, as shown in Fig. 37. Assemblies were loaded on 17-by-30-in. trays in lots of 300 for entry into the furnace.

Assemblies were brazed at 2050 F in an electric box furnace, in an exothermic atmosphere. Brazing time was slightly less than 12 min (time in the high-heat chamber), and one operator processed 1560 assemblies per hour. At this rate of production, the value of the steel saved by combining machining and furnace brazing amounted to more than $100 per hour.

Example 570. Simplifying Fabrication by Combining Machining and Furnace Brazing (Fig. 38)

Several features in the design of the fuel-injection pump-nozzle holder shown in Fig. 38 made it difficult and expensive to fabricate in one piece. It required an internally threaded round base to adjoin a smaller hexagonal section — a combination requiring several different machining operations and different machines. In the upper portion, it also required six 1/32-in.-diam holes extending from an outer shoulder to an inner recess.

To simplify fabrication and reduce cost, the nozzle holder was machined as two separate pieces, both of 1117 steel bar stock, in automatic bar machines. The threaded base was machined from 1-in.-diam round bar, and the upper portion, from ¾-in. hexagonal bar. The internal cavity was made by counterboring the hexagonal stock, and the six holes were drilled through the hexagonal body to connect with the counterbored recess.

A shoulder was machined on the base, and a matching counterbore on the upper portion, to nest the upper portion on the base. The nesting surfaces were machined to obtain a light interference fit (0.000 to 0.002 in. on diameter), for positive location and good flow of copper filler metal. A preformed hexagonal ring of BCu-1 copper wire was slipped over the hexagonal section to complete the assembly (see Fig. 38).

Assemblies were brazed in an electric box furnace at 2050 F, in an exothermic atmosphere. Production rate was about 1500 assemblies per hour.

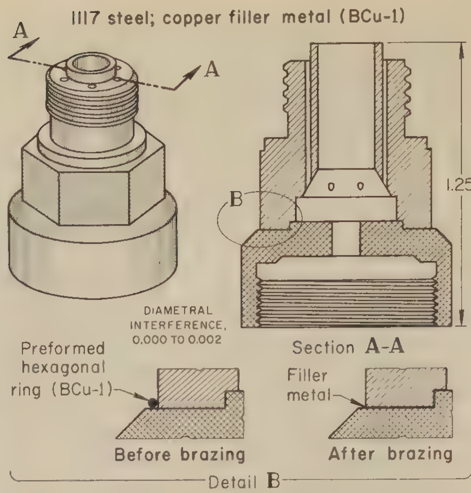

Fig. 38. Fuel-injection pump-nozzle holder that was produced as a brazed assembly of two components to simplify machining (Example 570)

Brazing Instead of Mechanical Fastening. Bolting, riveting, and staking are often replaced by brazing for applications where mechanically fastened assemblies are likely to be loosened by vibration. The example that follows describes an assembly for which brazing replaced staking to ensure against loosening.

Example 571. Brazing Instead of Staking To Prevent Loosening of Components in a Stop-Plate Assembly (Fig. 39)

The assembly shown at the top of Fig. 39, of which all components were of 1117 steel, functioned as a governor stop for a fuel-injection pump on a diesel engine. The threaded stud served as a means of moving the stop block back and forth, as needed, to adjust for maximum engine speed. The stop surface was opposite the side to which the pin and stud were attached. Assemblies were brazed in the position shown in Fig. 39, but they operated with the stud horizontal and the stop surface vertical. The pin served as a guide, and prevented radial movement of the stop block. All forces were compressive and against the shoulder of the stud, which meant that the assembly could have operated without fastening (beyond pressing the components together) had it not been for the vibration to which it was subjected.

Originally, the pin and stud were pressed into the block and staked. But, in several instances, the parts loosened from vibration; on one occasion, the assembly fell apart, resulting in a runaway engine.

To prevent any further accidents, the assembly was furnace brazed, using 0.020-in.-diam copper wire as filler metal, a box-type (pusher) furnace at 2050 F, and an exothermic atmosphere. The assemblies were loaded on Inconel trays for brazing. Time in the brazing chamber was about 12 min. It was possible to braze about 1500 assemblies per hour.

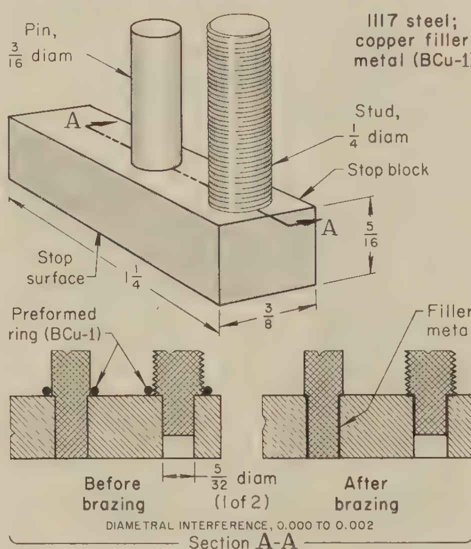

Fig. 39. Stop-plate assembly for a fuel-injection pump. Originally, the pin and stud were secured in the block by staking, but a change was made to copper brazing to ensure against loosening. (Example 571)

Substitution for Forging or Casting. Furnace brazed assemblies comprising two or more separately machined components may be more economical to fabricate than a complex forged or cast component that requires extensive machining. Cost savings result from the elimination of expensive punch and die sets (with limited life), elimination of one or more difficult machining operations, or overcoming a high rejection rate resulting from porosity and other defects in the cast product, as illustrated by the applications described in the following examples.

Example 572. Reduction in Machining Costs by Substitution of a Furnace Brazed Assembly for a Machined Forging (Fig. 40)

Originally, the tappet-shell assembly shown in Fig. 40 was finish machined from a single forging. The forging was produced in a hot upset forging machine, with the punch partly forming the contoured recess. Punch life was poor, and wear on the punch made it difficult to produce forgings that were within dimensional requirements. Even acceptable forgings required extensive machining, including a difficult and costly end-mill profiling operation on the contoured recess.

Production costs were greatly reduced by machining the shell and disk as separate components, assembling, and furnace brazing. Both components were machined from 1118 steel bar stock. The shell was machined from 1-in.-diam bar stock in an automatic bar machine by drilling the body and counterboring one end to receive the disk. After they were cut off, 25 shells were placed end-to-end, and the contoured recess was broached in a single operation. The shells were then placed side-by-side for broaching the top slot.

The disks were machined from 13/16-in.-diam bar stock by turning and by chamfering one edge. The counterbore in the shell was machined to provide a diametral interference fit of 0.001 to 0.003 in. with the disk. During assembly, a preformed ring of 0.032-in.-diam BCu-1 copper filler-metal wire was placed in the circular cavity between the chamfer on the disk and the inner wall of the shell, and the shell was forced over the disk by use of an arbor press.

The assemblies were loaded, disk side down, on 11-by-32-in. trays, 200 assemblies per tray. Each trayload of assemblies was brazed at 2050 F in an electric box furnace for 15 min, in an exothermic atmosphere. Production rate was 800 assemblies per hour per furnace.

Example 573. Substitution of a Furnace Brazed Assembly for a Casting To Eliminate Leakage (Fig. 41)

Originally, the leakoff-valve assembly shown in Fig. 41 had been produced as a single machined brass casting, but porosity of the casting resulted in leakage in service, and so the method of producing the leakoff valve was changed to assembly by furnace brazing of two pieces machined from 1113 steel bar stock.

The components of the assembly were turned and partly drilled in an automatic bar machine; the transverse hole was drilled in a drill press. The components were assembled, and filler metal in the form of a preformed ring of copper wire (BCu-1) was slipped over the inserted component and located, as shown in Fig. 41. Assemblies were then loaded on furnace trays, with the inserted component upright.

The assemblies were brazed at 2050 F in an electric box furnace, in an exothermic atmosphere. After brazing, drilling was completed and the hole in the inserted component was threaded.

APPENDIX 1

Safe Operation of Brazing Furnaces

By H. M. WEBBER*

In starting up, operating, shutting down, and maintaining brazing furnaces that contain protective atmospheres, it is important that correct procedures be followed for the safety of personnel and equipment. Safety features are available to help guard against making unfortunate mistakes, but the best safety feature of all is a well-trained operator who thoroughly understands the equipment, the nature of the gases utilized, and the importance of correct procedures. An operator who understands these fundamentals will be well equipped to understand supplementary instructions for specific types of furnace equipment,

*Manager of Process Engineering, Harper Electric Furnace Corp.

The original manuscript of this Appendix was reviewed by: James T. Blackmon, Jr., Chairman, Ovens and Furnaces Committee, National Fire Protection Assn.; D. P. Congdon, Executive Engineer, Factory Insurance Assn.; and Frank C. Poehlman, Engineer, Factory Mutual Research Corp. The author acknowledges with thanks the suggestions of the reviewers.

and will be capable of operating the equipment with safety and confidence.

Nonflammable gases will not burn in air, or explode if mixed with air in any proportions, when exposed to temperatures that can ignite flammable mixtures. Typical nonflammable gases are nitrogen, argon, helium, and carbon dioxide, and mixtures of these gases containing small percentages of flammable gases, such as hydrogen and carbon monoxide.

Lean exothermic gas is a typical mixture of nitrogen and carbon dioxide that contains low percentages of hydrogen and carbon monoxide. A maximum of 1% hydrogen and 1% carbon monoxide will be safely below the minimum amounts of hydrogen and carbon monoxide in room-temperature mixtures of lean endothermic gas with air that can explode when ignited by hot furnace components (see "Flammable Gases", below). Heated mixtures in a warm furnace can be ignited more readily, but the 1% limits mentioned above will still suffice. Mixtures that do not exceed these maximums can be considered nonflammable.

The nonflammable gases can be used freely in furnaces without hazard of explosion in all mixtures with air, with furnace heat on or off, or with pilots lighted or unlighted. Caution should be observed with carbon monoxide, however, because of its toxic effect, discussed below under "Carbon Monoxide Poisoning and Suffocation Hazards", and with gases heavier than air — namely, argon and carbon dioxide — which can flow out of furnaces and lie low to cause suffocation.

Flammable Gases. The most potent flammable gas commonly encountered in furnace atmospheres is hydrogen. Others are carbon monoxide and methane (CH_4). Flammable prepared mixtures containing hydrogen, carbon monoxide and a small amount of methane, together with percentages of nonflammable gases, include rich exothermic gas, purified rich exothermic gas, and endothermic gas. Dissociated ammonia (75% H_2, 25% N_2) is, of course, highly flammable.

When a brazing furnace chamber contains 3% or less of hydrogen and a similar amount of carbon monoxide, or more than 75% of hydrogen and carbon monoxide, it is safe from explosion if mixed with air at ignition temperatures.* However, all in-between percentages of flammable gas mixed with air can explode with considerable violence, producing pressure, heat and flames that can destroy or damage equipment and injure or kill personnel. It is most important that the furnace operator understand these basic principles, and that he take precautions to see that ignition, such as may result from turning on the heat or lighting the pilots, does not take place except under *known safe* conditions.

Test results indicate that hydrogen-air mixtures can be explosive at room temperature and can be ignited by a hot spark in a glass tube when the hydrogen content is as low as 4%, or as high

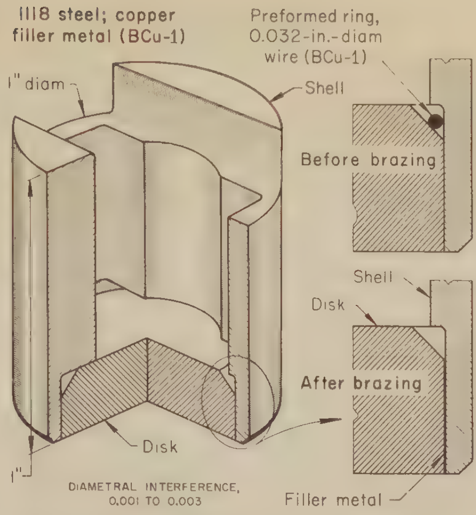

Fig. 40. Tappet shell that was produced as a two-piece brazement instead of a forging, to decrease cost of machining (Example 572)

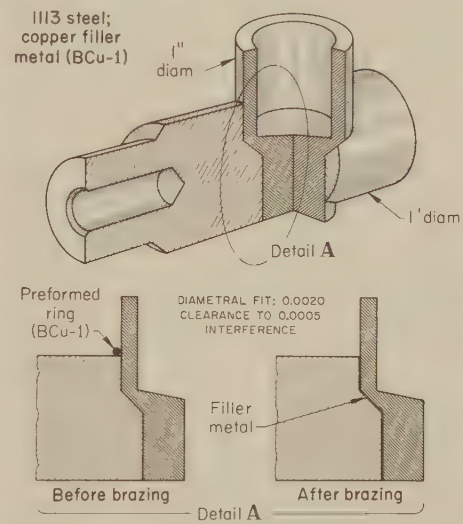

Fig. 41. Leakoff-valve assembly that was changed from a brass casting to a two-piece steel brazement, to avoid leakage due to porosity in the casting (Example 573)

as 75%, by volume. If the mixture is heated before ignition, the low limit decreases and the high limit increases as the temperature increases. Therefore, it is suggested that all concentrations of hydrogen *in excess of 2%* be considered flammable. Although the room-temperature upper flammable limit of a mixture of hydrogen in air is 75% hydrogen, the remaining 25% is air made up of 21% oxygen and 79% nitrogen, and at room temperature, a hydrogen-air mixture containing oxygen in amounts of 5% or more is explosive. At elevated temperatures, the dangerous oxygen level decreases to 3%. In mixed gases containing air, a carbon monoxide content of 12% or more by volume is explosive at room temperature; the explosive level decreases to 9% carbon monoxide at elevated temperatures.

In laboratory tests to determine explosive limits, electric hot sparks have been used as sources of ignition, as mentioned. In brazing furnaces, however, the ignition source can be a hot heating element, hot muffle, or some other component. Also, static electricity may be present where there is gas flow, which presents the possibility of an electric static discharge.

Ignition Temperatures. The minimum ignition temperature of hydrogen in air or oxygen is about 1065 F (574 C). For carbon monoxide, the ignition temperature is about 1202 F (650 C). Thus, an explosive mixture will ignite if exposed to these temperatures or to higher temperatures. If a furnace is to be purged by the burnout method, as discussed in a later section of this Appendix, these combustible gases should not be fed to the furnace until the furnace temperature is 1400 F (760 C) or above, thereby ensuring ignition of the combustible gases as they enter the air-filled furnace.

Purging is the replacement of one atmosphere in a furnace or retort with another atmosphere, in such a manner as to prevent the formation of an explosive mixture. In brazing furnace operation, at start-up, the air in the furnace or retort is replaced with a nonflammable gas, followed by a flammable protective-atmosphere gas, or the burnout method is used. At shutdown, the flammable furnace-atmosphere gas is replaced by a nonflammable gas (or the burnout method is used), followed by filling the furnace or retort with air. Purging with nonflammable gases and by the burnout method is discussed in subsequent sections of this Appendix.

Critical Periods

In operating a furnace containing a flammable protective atmosphere, there are four potentially critical periods:

1 When introducing the flammable protective-atmosphere gas into the furnace chamber
2 When opening a cold chamber filled with flammable gas
3 When removing the flammable atmosphere gas and allowing air to re-enter the furnace
4 When the flow of flammable gas to the furnace is accidentally interrupted during otherwise normal operation.

Items 1 and 3, which relate to purging, are discussed in subsequent sections of this Appendix; items 2 and 4 are considered in the next two sections.

Cold Chambers

Cold chambers (such as water-jacketed horizontal cooling chambers attached to heating chambers, and cooling bells) containing flammable atmospheres are hazardous unless adequately protected and properly operated. To ignite the flammable atmosphere gas safely as it contacts the room air, and to prevent the formation of an explosive mixture inside the chamber, placement of gas-flame pilots and flame curtains at the end doors is highly recommended. If possible, end doors should be opened a minimum height to inhibit infiltration of air. If end doors that are normally closed are constructed to be sloping rather than vertical, they will allow faster ignition of the atmosphere gas as it leaves the furnace when they are opened. Room drafts arising from open doors and windows should be kept to a minimum.

*Wilbert J. Huff, Gaseous Fuels, "Chemical Engineer's Handbook", Third Edition, McGraw Hill Book Co., 1950, p 1584, 1585, 1586.

If possible, the furnace should be situated so that the normal room drafts are crosswise to, rather than parallel with, the length of the furnace. Ventilating fans and room inlets for makeup air should be strategically located for this purpose. Baffles may have to be erected at vital points near the furnace to block normal room drafts, or to divert unexpected drafts.

Emergency Procedure When Flow of Flammable Gas Is Interrupted

Whenever flow of flammable gas to the furnace is interrupted, the operator should make an immediate attempt to re-establish flow. If this is not possible, and flow cannot be restored immediately, the furnace should be purged, by either the nonflammable-gas method or the burnout method, to ensure maximum safety. The type of furnace and the degree of flammability of the gas may affect the time delay permissible before purging, but the recommended procedure is to immediately, and automatically, start purging with nonflammable gas and to sound an alarm.

If an emergency supply of nonflammable gas is not available and the flow of flammable atmosphere gas cannot be restored promptly, the burnout method of purging should be used. For box and other straight-through furnaces, continuously burning gas pilots will supply a source of ignition. If these are not available or are not operative, portable torches should be used, or twisted newspapers or oily waste should be laid across the full width of outside door openings and lighted. Then the doors should be partly opened. The pilots, torches, newspapers or waste should be kept burning until the residual gases are burned out.

For a bell or elevator type of brazing furnace, with retorts, it is recommended that nonflammable gas be made available, and that an automatic system be provided to purge the retorts with nonflammable gas in the event of failure of flammable-gas supply, and to sound an alarm.

Leaky Gas Valves

Safety shutoff valves and manual shutoff valves in flammable-gas lines have been known to leak when closed. Such leaks can, of course, allow flammable gas to seep into the furnace chamber, muffle or retort during standby periods, when it is assumed that the furnace is free of flammable gas. Gas-valve leaks are potentially dangerous. For example, if a small leak should supply flammable gas to an air-filled furnace or cooling chamber over an extended shutdown period while the furnace is cold, an explosive mixture could develop. This mixture could be ignited when the furnace heat was turned on at start-up, prior to purging. Ignition could trigger a dangerous explosion. Several simple precautions can be taken to minimize or prevent explosions caused by leaky valves, the best of which is to provide "block-and-vent" valves. First, there should be a safety shutoff valve in the flammable-gas line, followed by a normally closed solenoid-operated (or, if preferred, safety shutoff) blocking valve. The interconnecting pipe between these valves should have joined to it a venting line running to the outdoors at a safe location, and the venting line should be equipped with a solenoid-operated vent valve that is normally open. When the two mainline valves are open, the vent valve should be closed. When the mainline valves are closed, the vent valve should be open to permit drain-off of any flammable gas that might leak through the closed safety shutoff valve.

Table 6. Nonflammable Gases Used for Furnace Purging

Gas	Specific gravity(a)
Argon	1.379
Carbon dioxide	1.527
Helium	0.137
Nitrogen	0.972
Lean burned dissociated ammonia ($99\ N_2$, $1\ H_2$)	0.963
Lean exothermic gas	1.030
Lean purified exothermic gas	0.966

(a) Specific gravity of air is 1.000.

Leaky Retorts or Muffles

Leaks in furnace retorts and muffles invariably provide their own warning signals: deterioration in the appearance and quality of the work and an appreciable increase in the dew point of the atmosphere within the retort or muffle. Nevertheless, all retorts and muffles should be pressure or vacuum tested periodically, and whenever a leak is detected, it should be repaired promptly.

When a muffle can be removed from the furnace, it can be tested more conveniently without the encumbrance of the surrounding furnace. However, many muffles are built into the furnace and are difficult to remove. Testing a built-in muffle often can be accomplished by removing the mesh belt and by sealing the extreme ends of the furnace for pressure or vacuum testing. The sealing is generally accomplished by clamping steel plates with gaskets to the entrance and exit ends of the furnace.

When it is suspected that a muffle is leaking and the furnace is in operation at high temperature, the hot chamber should be permitted to cool down to 1400 F and should then be purged with nonflammable gas or by the burnout method, as described in the sections on purging in this Appendix.

Carbon Monoxide Poisoning and Suffocation Hazards

The possibility of carbon monoxide poisoning is always present in the vicinity of a protective-atmosphere furnace or gas generator when the atmosphere gas contains carbon monoxide. Usually, the atmosphere gases coming from furnaces are satisfactorily controlled by adequate room ventilation or by exhaust systems, or by burning the escaping gases at flame curtains. However, if the ventilation or exhaust is poor, or if atmosphere gases containing carbon monoxide are not burned at furnace openings, there is a definite hazard.

Because carbon monoxide is colorless, odorless, tasteless and nonirritating, a person inhaling air contaminated with carbon monoxide receives no warning of its presence. He should, therefore, be warned of the toxic effects of carbon monoxide and be acquainted with the symptoms of its effects.

A comparatively small concentration of carbon monoxide can have a marked effect on a person. According to Bureau of Standards Technical Paper 212, safe concentrations of carbon monoxide in air are less than 0.01%. Exposure to 0.04% for about 1½ hr may produce the characteristic primary symptoms of headache, mental dullness, and physical loginess. Greater concentrations or longer exposure times may prove fatal. Accordingly, when symptoms are noted, personnel should leave the area at once and report the condition to the proper authorities. Simple and inexpensive testing equipment for detecting carbon monoxide and warning of its presence is available. If safe limits of carbon monoxide are to be established for given working environments, medical authorities should be consulted.

If personnel are to enter a furnace that has been shut down for repairs, particular care should be taken to ensure that all gases, particularly (but not exclusively) those containing carbon monoxide, are first flushed out of the furnace with air. In addition, a continuous flow of fresh air from a fan or blower should be provided to the furnace during the repair periods. For safety, some users require that atmosphere-gas supply lines be disconnected from the furnace gas-inlet lines during repair periods. This eliminates the hazard of depending on shutoff valves, which might leak.

Suffocation and death can occur from lack of oxygen, either within or outside the furnace. As gases that are heavier than air — namely, argon and carbon dioxide — flow out of the furnace, they lie near the floor and can cut off the supply of oxygen.

Purging With Nonflammable Gas

These recommendations apply to all types of furnaces with protective-atmosphere heating chambers, with or without muffles or retorts, rated at any temperature, and heated by all types of heat sources. Where practical, it is preferable to purge an air-filled furnace with nonflammable gas prior to introducing a flammable-gas atmosphere. Likewise, during shutdown, it is preferable to purge the flammable gas with nonflammable gas. This applies particularly to heated furnaces, or sections of furnaces, that are below the generally reliable gas-ignition temperature of 1400 F (760 C). Flow-rate indicators and a time clock should always be used to ensure complete nonflammable-gas purging, and a method for checking the extent of purging is often highly desirable.

When air is purged from a furnace chamber using nonflammable gas, a volume of nonflammable gas equal to about five volumes of the chamber may be needed to reduce the oxygen content to about zero per cent. For maximum safety, most operators observe the five-volume rule. Typical nonflammable gases used for purging are listed in Table 6. The extent of purging by removing air with nonflammable gas can be determined with the use of an oxygen analyzer or a specific-gravity indicator. The same specific gravity indicator can also be used to determine the extent of purging flammable gas with nonflammable gas when the furnace is being shut down.

The density of the purging gas has some bearing on the purging procedure. When a chamber is purged by replacing one gas with another, the least amount of mixing is generally desirable and permits the most rapid and economical purging. If the density of the two gases is approximately the same, as, for example, air (sp gr 1.0) and nitrogen (sp gr 0.972) or lean exothermic gas (sp gr 1.03), it will make little difference as to the manner in which the two gases are brought together, and therefore, if the air in a chamber is to be displaced by nitrogen, the nitrogen can be introduced at the top or at the bottom, whichever is more convenient, assuming that there is an opening at the opposite extremity for allowing the gases to escape.

If, however, it is desired to replace air (sp gr 1.0) with helium (sp gr 0.137), it is preferable to introduce the helium at the highest level, so that it can collect at the top and force the heavier air out at the bottom, with a minimum amount of mixing of the two gases. If the purging gas is argon (sp gr 1.379) or carbon dioxide (sp gr 1.527), the purging gas should be introduced at the bottom, so that the lighter air can escape at the top. The same principle applies when shutting down a furnace or taking a retort out of service, when it is necessary to replace the flammable gas with a nonflammable purging gas.

In some furnaces, it may be impractical to employ the density consideration, and the gases may have to be diffused with turbulence and mixed, regardless of specific gravity, in order to replace one with the other. In general, this can be done satisfactorily, but it is likely to involve more time and greater expense.

Follow-Up Purging With Flammable Gas. After purging with nonflammable gas and before starting up, the next step is to purge with flammable gas. Here, too, about five volume changes will generally ensure complete purging. Purging with flammable gas also should be measured with flow-rate indicators and a time clock, to ensure complete replacement.

Some typical flammable gases and their specific gravities are shown in Table 7. All of the flammable gases in Table 7 are lighter than the nonflammable gases in Table 6, except for helium.

When it is assumed that the chamber is completely purged with flammable gas, it is highly recommended that the composition of the effluent from the furnace be checked, using one of the methods listed in the following paragraph, to make *sure* that it is not explosive, before turning on the heat, lighting pilots, or providing a source of ignition in any other way. Such routine checks may seem to be of little value when other prescribed procedures are adhered to, but they can show up a rare mistake by the operator or a fault in the equipment and will help to prevent an explosion that might otherwise occur. For example, the furnace operator could forget to purge with nonflammable gas prior to injecting the flammable gas; the flow rate or time interval for either of the purging gases could be inadequate; or an unnoticed crack in a retort or muffle, or an open door or pipeline, could provide a source of unwanted air.

Table 7. Flammable Gases Used for Furnace Purging

Gas	Specific gravity(a)
Hydrogen	0.069
Dissociated ammonia (75 H_2, 25 N_2)	0.295
Dissociated ammonia burned with air, rich (24 H_2, 76 N_2)	0.755
Rich exothermic gas:	
Unpurified (15 H_2)	0.858
Purified (15.5 H_2)	0.825
Endothermic gas:	
Dry (38 H_2)	0.622
Wet (28 H_2)	0.798

(a) Specific gravity of air is 1.000.

Several methods are available for determining whether the flammable gas in the cold chamber is safe or explosive. A specific-gravity indicator is effective for this purpose. An oxygen analyzer of the proper type can also be used. Some oxygen analyzers operate on a combustion principle, which would supply a hazardous source of ignition to an explosive atmosphere. Safe instruments are the chemical-absorption type and the magnetic-susceptibility type of oxygen analyzers, which provide no source for ignition. An atmosphere sample can be collected in a test tube and ignited at a safe distance from the furnace. Quiet burning or a pop or whistle will indicate its nature. After it has been determined that the furnace is safely filled with flammable gas, and there is no chance for the atmosphere to explode, it is safe to turn on the heat, to light pilots, or otherwise to subject the furnace atmosphere to ignition sources.

Purging by the Burnout Method

The burnout method of purging is utilized where it is impractical to purge an air-filled furnace with nonflammable gas before a flammable-gas atmosphere is introduced during start-up, or to purge out the flammable gas with nonflammable gas during shutdown. The following procedures apply to horizontal furnaces with heating chambers rated at 1400 F or above, with attached relatively cool chambers that may or may not be heated for preheating, burn-off, purging and cooling. These procedures do not apply to furnaces with molybdenum or tungsten heating elements, because such elements are seriously damaged in an air atmosphere at 1400 F or above. Furnace types covered include box, pusher, mesh-belt conveyor, and roller-hearth conveyor.

In the burnout method of starting up, a flammable gas is injected directly into the air-filled heating chamber after the chamber has been heated to approximately 1400 F. Care must be taken not to inject the gas into adjoining air-filled cool chambers, where explosive mixtures could form. If the main heating chamber has a muffle, these instructions apply only if a gas inlet leads directly into the muffle.

Start-up safety can be ensured by having a safety shutoff valve in the flammable-gas line to the furnace interlocked with a 1400 F contact in a furnace temperature-control instrument. This arrangement ensures that only when the furnace is 1400 F or above can flammable gas be supplied to it. If the furnace temperature drops below 1400 F, the safety shutoff valve will close and stop the flammable-gas flow and sound an alarm. An auxiliary timer and solenoid valve in the atmosphere-gas line to the cooling chamber should allow flow only after adequate time has elapsed for complete burnout purging by the gas entering the heating chamber.

If the furnace operating temperature is to be below 1400 F, such as might be required for silver brazing, the foregoing procedure would need to be modified slightly. First, the furnace should be heated to 1400 F and purged as described in the preceding paragraphs. When that temperature has been reached, the auxiliary contact in the temperature-control instrument can be bypassed with a holding relay, and the temperature can be lowered safely without the contact closing the safety shutoff valve and cutting off the atmosphere-gas flow to the furnace. To shut down the furnace after use at reduced temperature, the furnace should be reheated to 1400 F and the burnout procedure followed as outlined below. Or, if the alternate nonflammable-gas procedure is preferred, shutdown can be instituted directly from the low operating temperature.

During start-up, as the flammable gas enters the brazing chamber, which has been heated to 1400 F or above, the gas burns oxygen out of the air. It continues to burn and to spread into adjoining chambers, eventually flooding the entire furnace and making it ready to operate with protective atmosphere.

During shutdown, the procedure is reversed. The flammable gas is ignited at an opened end door, and gas flow is shut off. As the gas burns, air sweeps in and the flammable constituents are entirely consumed, leaving the furnace filled with air and nonflammable products of combustion.

Procedures for Start-up and Shutdown, Using the Burnout Method

For convenience, the following lists present, in chronological sequence, the typical steps to be taken in starting up and shutting down a horizontal furnace of the box, mesh-belt, or roller-hearth type, using the burnout method. For a particular furnace, the manufac-

turer's operating instructions should be consulted and followed, since a typical procedure cannot be employed for all types and makes of equipment.

Procedure for Start-up

1 Open wide all furnace doors.
2 Make sure all inlets for flammable atmosphere gas are shut off tight, and have been so for some time. If there is any question that there has been some leakage, do not turn on the heat source or light any pilots or curtains. First blow or flow air or nonflammable gas into the furnace, taking particular care to purge high spots such as the arched roof and refractory door cavities. Vent the nonflammable gas outdoors, so that it cannot accumulate in areas where there are personnel.
3 Turn on heat and bring main heating chamber up to 1400 F (760 C), or above.
4 If there is a heated preheat or precool chamber attached, with muffle, bring it up to 1400 F also, preparatory to burning any flammable gas that might leak through pores or cracks in the muffle. If the maximum temperature rating is below 1400 F, or if there is no muffle, heating of this chamber is optional.
5 Close all purge and vent pipes.
6 Light all pilots at flame curtains, purge pipes and vent pipes.
7 If the hot chamber (or chambers) is double-ended and has an attached cool chamber (or chambers) at only one end, close the outer entrance door to the hot chamber, leave all intermediate throat-baffle doors wide open, and lower the outer exit door of the cool chamber to an opening of 2 or 3 in. For this purpose, gas-flame curtains should be adjusted to extend only slightly above hearth level to facilitate seeing the atmosphere-gas flames described in item 9 below.
8 If attached cool chambers are at both ends of the hot chamber (or chambers), leave all intermediate doors wide open and lower both outer entrance and exit doors to openings of 2 or 3 in. Adjust gas-flame curtains in accordance with item 7.
9 Start flow of flammable gas into hot (1400 F or above) main heating chamber, using a flow rate equivalent to normal consumption. Continue until atmosphere gas burns at the outer entrance and exit doors. The burning of gas at the furnace doors is an indication that all air has been burned out and that the furnace is filled with protective atmosphere.
10 Lower and raise intermediate refractory doors. Piston action in upper door cavities may create vacuum or pressure, causing air to rush in or gas to be pushed out forcefully at end openings. Slower door-operating speed will usually rectify this objectionable effect. Reduce speed of air-operated doors by closing down the small needle valves in vent lines of the pneumatic cylinders.
11 Open the outer end doors wide and adjust gas-flame curtains to full height to cover the openings completely with nearly transparent flame.
12 Close all outer end doors and intermediate doors, if so desired.
13 Open purge and vent pipes as desired. Atmosphere gas will be ignited by the pilots.
14 Bring temperature of heating chamber (or chambers) up or down to desired operating temperature.
15 As a drying-out procedure, allow time for heat to soak into refractory walls and moisture to be purged out of protective atmosphere.
16 The furnace should now be ready for operation.

Procedure for Shutdown

1 Adjust temperature of hot chamber (or chambers) to 1400 F (760 C) or above.
2 Open all interior doors wide.
3 Provide continuous, reliable ignition sources at both outer entrance and exit doors. These may be pilot lights, low-burning gas-flame curtains, or portable torches. The gas-flame curtains for this purpose should be adjusted to extend only slightly above hearth level to allow fresh air to sweep over them into the furnace after the outer end doors of the furnace are opened and the atmosphere gas is burning.
4 Partly open outer entrance and exit doors. Be sure atmosphere gas is ignited.
5 Shut off flow of flammable atmosphere gas to all inlets of hot and cool chambers. The ignited atmosphere gas will burn with insweeping air throughout the furnace, and the flame will extinguish itself in a few minutes.
6 Caution: *Make sure that all atmosphere-gas shutoff valves are closed tightly and do not leak.* Use of the block-and-vent valves previously described will ensure against leakage.
7 With the inner flame extinguished and all chambers filled with air and nonflammable products of combustion, all pilots and flame curtains may be extinguished and the heat source (or sources) shut off.
8 Leave all furnace doors open for self-venting in the event of leakage of flammable gas.
9 At this stage the furnace can be considered completely shut down.

APPENDIX 2

Application of Vacuum Furnace Brazing

Stainless steel heat-exchanger modules, the tubes and interconnecting fins of which are made by brazing together identical sections of corrugated strip in a stacked-honeycomb arrangement, are among the wide variety of assemblies fabricated from stainless steels, heat-resisting alloys, titanium, and refractory metals that are brazed in vacuum furnaces capable of developing a vacuum pressure of 10^{-7} torr and temperatures as high as 3000 F. These modules are used in the oil systems of large aircraft.

The main body, or stack, of the module is made up of sections of corrugated type 321 stainless steel strip 0.003 in. thick. Prior to brazing, the corrugated strip sections are preassembled and held in alignment by spot welds that are deposited along the fin sections separating corrugations. Nickel alloy filler metal (AMS 4778), in the form of powder, is mixed with an acrylic plastic binder and a thinner, such as acetone or xylene, and sprayed in precisely measured quantities on the backs of the sheets. The sheets are then arranged in stacks and are held in position by brackets that become part of the module assembly. When assembled, a typical module is a 12-in. cube. The modules are brazed at 1980 ± 20 F in accordance with the following procedure:

1 Eight modules are placed in the vacuum furnace.
2 A total of six thermocouples are attached to the thinnest and heaviest sections of the modules.
3 The furnace is sealed; pumpdown begins.
4 The furnace is heated; pumpdown continues to pressures of 10^{-4} to 10^{-5} torr.
5 Heating continues to 1075 F; to equalize, the furnace is held at 1075 F for 30 min.
6 Heating continues to 1675 F; to equalize, the furnace is held at 1675 F for 30 min.
7 Heating continues to brazing temperature, 1980 ± 20 F; furnace is held at this temperature for 5 min.
8 Furnace is backfilled with argon and fan-cooled to room temperature.

The total elapsed time for completion of the above cycle is 4 hr. Approximately 2000 joints are brazed on a single module.

Metals Brazed. The metals most commonly brazed in vacuum furnaces are the austenitic and martensitic stainless steels, solid-solution and age-hardenable heat-resisting alloys, titanium and titanium alloys, and refractory metals, such as columbium, tantalum and zirconium. The reasons for selecting vacuum brazing in preference to conventional furnace brazing under protective atmospheres vary considerably. For example, many of the age-hardenable heat-resisting alloys contain aluminum or titanium; these alloying elements, when heated, form refractory oxides that interfere with wetting and that cannot be reduced in reducing protective atmospheres, including dry hydrogen. Titanium, titanium alloys, columbium, tantalum and zirconium cannot be brazed in any of the protective atmospheres other than argon without suffering contamination and embrittlement, but argon does not ensure good wetting by the filler metal. Stainless steel assemblies, such as the heat-exchanger module, are brazed in vacuum partly to ensure complete purging of internal cavities. Often, brazing and heat treatment are combined in one operation.

Filler metals containing alloying elements with low boiling points or high vapor pressures are studiously avoided. Nickel-base, copper-base, gold-base, palladium-base, and a few silver-base filler metals are commonly used in vacuum furnace brazing. Metallic impurities in all these filler metals are rigorously controlled. Apart from compatibility with the base metal, filler metals are invariably selected for corrosion resistance in specific media and suitability for service at known operating temperatures. Pure copper, for example, is seldom used as a filler metal, because its upper temperature limit for continuous service is only 400 F (as compared to about 800 F for gold filler metals and about 1200 F for nickel filler metals). Many of the filler metals in common use are nonstandard, as for example, those containing 92% gold and 8% palladium; 50% gold, 25% palladium and 25% nickel; and 65% silver, 20% copper and 15% palladium.

The amount of filler metal applied to the joint area is usually carefully controlled for two reasons: (*a*) wetting action is excellent, and excess filler metal flows without hindrance to areas where it is neither needed nor wanted; and (*b*) excessive interalloying of base metal and filler metal is often harmful to joint strength.

Furnaces. Both hot wall (retort) and cold wall (radiant shield) furnaces are used in vacuum brazing; however, because of inherent advantages, cold wall furnaces are by far the more widely used. Cold wall furnaces heat faster and with greater efficiency, and are suitable for use at higher temperatures and vacuum pressures. For example, the upper operating temperature limit for a hot wall furnace is about 2200 F, as compared to about 3000 F for a cold wall furnace. At the higher operating temperatures, the ability of the retort of the hot wall furnace to resist collapse is increasingly dependent on the supporting vacuum surrounding the retort.

Other Examples of Furnace Brazing in This Volume

Metals brazed	Example
Aluminum alloy 6061	633
Copper alloy 102	634
Copper alloy 102 to molybdenum	638
Copper alloys 220 to 122; 172 to 340, 220 and 172	636
Copper alloy 757	637
Copper to fine silver	635
Gray iron	612
Gray iron to steel	613
Stainless steel, type 347	616, 617, 619
Stainless steel, types 303 and 305 to PH 15-7 Mo	618
Stainless steel, type 410	620, 621
Stainless steel, type 304 to 403	622
Stainless steel, type 304 to 17-7 PH and to copper alloy 145	623
Stainless steel, type 302 or 430	624
Stainless steel, type 347, to titanium	625
Stainless steel, types 304 and 446, to copper alloys	626

Torch Brazing of Steel

*By the ASM Committee on Brazing of Steel**

TORCH BRAZING is a brazing process in which the heat is obtained from a gas flame or flames impinging on or near the joint to be brazed. Torches used in this process may be of the hand-held type or may consist of fixed burners having one or many flames. Several types of fuel gas are available for combustion with oxygen or air. Torch brazing can be done as a completely manual, a partly mechanized, or a completely automatic process.

This article deals mainly with the torch brazing of carbon and low-alloy steels. In addition to the steels discussed here, torch brazing is used on stainless steels, aluminum alloys, copper and copper alloys, and magnesium alloys. Highly alloyed steels, heat-resisting alloys, and reactive metals are usually brazed by other methods, because they require special atmospheres or closer control of the thermal cycle, or both.

Manual torch brazing is best applied where production quantities are small, since equipment cost is low. It is also used in applications where physical size, joint configuration or other considerations make it difficult or impossible to braze by other methods. The main drawbacks are the high labor content and the relative skill needed for efficient production. Where production quantities are larger, automatic torch brazing is used, often producing brazed assemblies at the rate of 400 to 1400 per hour.

Fuel Gases. Acetylene, natural gas, propane and proprietary gas mixtures are the types of fuel gas most often used in the torch brazing of steel. Hydrogen, butane and producer (city) gas are seldom used. In manual torch brazing, pure oxygen is chiefly used as the combustion agent because of its fast heating rate. As a cheaper source of lower-grade oxygen, compressed air can also be used, if lower flame temperatures and heating rates are acceptable. Either oxygen or compressed air is used in automatic torch brazing.

The economics of gas consumption plays an important role in the selection of gases. The increased production of oxygen for steelmaking and other purposes has resulted in larger supplies and lower prices. This trend has favored the use of natural gas and propane, which require larger oxygen-to-fuel ratios than acetylene, but are themselves less costly than acetylene.

Compressed air involves only the cost of compression, and advantage can be taken of this in automatic operations, where the investment in pumping and mixing equipment can be amortized with the rest of the equipment. Another factor favoring compressed air – natural gas combustion in automatic applications is that if conveyor malfunction occurs, the workpieces will not be destroyed by overheating.

Torch Brazing Principles and Technique

The principles of torch brazing differ from those of other brazing processes only in technique. The braze bond is the same; a suitable filler metal is melted in a closely fitted joint between unmelted base-metal parts and fills the joint by capillary action.

Brazing Filler Metals. The two types of filler metal established as suitable for torch brazing of steel are the silver alloys and the copper-zinc alloys described in the section on Filler Metals starting on page 627. The silver alloys are more costly but, in general, melt at lower temperatures than the copper-zinc alloys. The tensile strength of the silver alloy filler metals is about half that of the low-carbon steels, but considerably greater strength is developed when they are used in correctly designed joints. Tensile strengths of the copper-zinc filler metals are about the same as that of low-carbon steel.

Joint Design. In torch brazing of steel, the commonly used filler metals need a joint clearance (at brazing temperature) of 0.002 to 0.005 in., for capillary flow. Where thermal expansion is significant, an allowance is made on room-temperature measurements. Lap joints designed for shear loads are preferred to butt joints designed for tensile loads. Six designs for brazing of lap joints are compared with their counterparts commonly used for welding in Fig. 31 in the article on Furnace Brazing. For maximum joint efficiency, the length of the overlap should measure at least three times the thickness of the thinnest member to be joined.

Joints are designed either for face feeding or for preplacement of filler metal. Preplacements are used in joints of large area or of a configuration difficult to penetrate by face feeding. For additional discussion of joint fit and design, see pages 607 to 610 in the article on Furnace Brazing.

Prebraze Cleaning. Filler metal will not wet and adhere to contaminated surfaces. Before torch brazing, the joint surfaces must be cleaned to remove all dirt, oil, grease, rust and scale. Prebraze cleaning is discussed on page 602 in the article on Furnace Brazing.

Fluxing. A flux is applied to the joint before heating, to promote the flow and bonding of filler metal throughout the joint to be torch brazed. Flux may be applied as a powder, paste, or liquid, or as a mixed paste of flux and filler metal. It may also be applied as a vapor, through the gas flame. The types of fluxes used are discussed in the section beginning on page 628 in this article.

In order to prevent oxidation of the joint surfaces, flux must be applied so that both surfaces to be joined are completely protected as the heating operation begins. Flux is effectively applied before assembly, especially if the joints are more than about $\frac{3}{16}$ in. deep. This is done by brushing a thin layer of paste on the cold or slightly warmed joint surfaces, or by dipping the joint in paste flux heated to about 200 F or in liquid flux. Paste or liquid flux may also be applied on the joint after assembly, if sufficient distribution can be obtained as heating begins.

The latter method is frequently used in automatic torch brazing; the dependence on joint design of fluxing before or after assembly can be seen by comparing Examples 580 and 581.

Flux is often applied on the area around the joint to minimize discoloration and scaling of the workpiece surface. Although this increases flux cost, postbraze cleaning time may be reduced or eliminated. When flux is used for this purpose, it should be applied sparingly to the entire surface that normally would oxidize on heating.

Flux inclusions can be caused by the application of too much flux, by too loose a joint fit, or by overheating the workpiece. When recognized in time, these conditions often can be remedied by moving one member in relation to the other during brazing, before the filler metal solidifies. The movement will aid the filler metal in displacing the flux and in penetrating the joint area.

The filler metal also should be protected by flux. Preformed filler metal can be dipped in flux or flux can be brushed onto it. Either face-fed rod, wire or strip can be brushed with flux, or the heated end can be dipped occasionally into dry flux powder. Filler-metal powder is either dusted on wet flux or mixed with it (see the section on Filler Metals in this article).

It is important that the flux be heated to its active state and that it flow over all joint surfaces before the filler metal starts to flow. Because some oxide forms during heating, a true braze bond will not occur on surfaces that have not been fluxed, even though the joint may appear to be adequately brazed. Usually, the filler metal flows around areas not protected by flux, resulting in voids.

Heating. Brazing should be done away from drafts, to avoid uneven heating and cooling. Torches adjusted for a slightly reducing or a neutral flame are used in bringing steel parts to brazing temperature. To prevent overheating and melting of the base metal, the torch tip is held away from the surface of the work so that the inner cone of the flame does not ap-

*For committee list, see page 593. About half of the examples presented in this article were contributed by members of other Metals Handbook welding and brazing committees.

proach too closely. Heating is accomplished by the outer flame envelope. In manual torch brazing, the torch should be kept in motion to avoid localized overheating. The flame should be applied so that both members of the joint are brought to uniform brazing temperature, as follows:

1 With joint members of unequal mass, heat the more massive member first, until flux melting indicates that brazing temperature has been reached.
2 Heat the less massive member next, until it reaches brazing temperature.
3 Heat the joint last, being careful not to overheat. If preplaced, the filler metal should flow all around the joint, appearing at the joint edges, and the flame should be removed. If face fed, the filler metal should be placed on the joint before or behind the point where the flame strikes the part.
4 Avoid applying the torch heat directly on the filler metal, if possible.

In some applications, a massive member may receive all of the heating, the less massive part being heated entirely by conduction. When joining steel to another metal, the metal having the higher thermal conductivity is treated like a more massive member.

When the fit between an inner and an outer member of a joint is not as tight as desirable for brazing, the flame is applied first to the inner member, where it emerges from the outer member, in order to expand the inner member and tighten the fit. Heating then is concentrated on the outer, or more massive, member, and further heating of the inner member is mainly by conduction. Conduction will be poor if the fit is not tightened by first heating as described.

Heating should continue until the workpieces are slightly hotter than the flow temperature of the filler metal. Overheating should be avoided; excess heat will break down the flux and interfere with its action.

Brazing fluxes melt at somewhat lower temperatures than the filler metals with which they are used. Their melting serves as an indication that brazing temperature is being reached. When flux is heated, the water content first boils off leaving a powdery deposit. Upon further heating, the flux melts as a clear, thin liquid, which flows through the joint and actively protects the surfaces from oxidation. If the rules enumerated above have been followed, the joint will be at brazing temperature, and the filler metal (if face fed) will melt and very quickly flow into the joint, after contact. If the filler metal does not melt and flow after contact with the base metal, the joint is not at brazing temperature and heating must be continued.

The braze cannot be made by melting the filler metal in the flame before the joint is at brazing temperature, because capillary flow will not occur. Instead, the filler metal will accumulate on the surface. Continued heating of the filler metal, in an attempt to induce flow, may alter the alloy composition. This improper procedure is one of the most frequent causes of poor brazing results. Furthermore, melting the filler metal in the flame may be hazardous to health because toxic fumes may be generated. The heat in the workpiece should always be used to melt the filler metal.

Feeding Filler Metal. The filler metals used in torch brazing of steel are chiefly of two types: silver alloys and copper-zinc alloys. Their characteristics are discussed in the sections on Filler Metals in this article. The filler metals are usually available in several of the following forms: rod and wire of various diameters, strip (shim stock) of various thicknesses, and powder.

The quantity of filler metal required per joint depends on the volume of the joint space to be filled plus the volume of the desired fillets. Usually the joint is slightly overfilled to allow for filler-metal shrinkage. In manual face feeding with rod or wire, the size of the filler metal used should be large enough to avoid interruption of brazing to start a new length. For thin materials, the diameter of the rod or wire should be comparable, if possible, to the thickness of the thinner joint member, since thicker filler metal would melt too slowly.

Automatic face feeding of wire and powdered filler metals is described in the section on Equipment for Automatic Torch Brazing in this article; the preplacement of wire, strip and powder is discussed in the section on Filler Metals.

Quality Control and Inspection. Joint quality can be controlled by carefully checking the adequacy of each of the procedural steps involved. Inadequate cleaning, improper joint clearance, underheating and overheating are common sources of difficulty. Defects that are likely to recur are usually in the form of voids due to: (*a*) unreduced oxide or foreign matter that prevents wetting of the joint surface, (*b*) gas pockets resulting from gas evolution or vaporization of lower-melting constituents of the filler metal, (*c*) entrapped flux, (*d*) incomplete filler-metal flow, and (*e*) too short a heating time.

Small and widely distributed voids seldom affect the serviceability of the part adversely. Most inspection standards require no more than 80% coverage between faying surfaces, as revealed by peel testing or radiography.

Visual inspection is frequently used: joints are accepted if a continuous fillet is formed all around the joint, especially on the side opposite to that of filler-metal placement or feeding.

Pressure tests and radiographic examination are used to reveal defects nondestructively. In addition, destructive testing can be used both to set up the original procedure and, on a sampling basis, to check whether the procedure is under control. One form of destructive test is the peel testing of lap joints, frequently used in resistance spot welding. To make this test, one member of the joint is held in a vise while the joint is opened with a chisel, and the other member is then peeled or twisted away to reveal the condition of the bonded area.

Brazing vs Braze Welding. One of the joining methods often confused with torch brazing is the operation known as braze welding. The equipment and certain of the filler metals used in this type of joining may be the same as those used in manual torch brazing. In some applications, even the torch and filler-metal manipulations may appear the same. In general, the two joining methods differ considerably. Some of the characteristics of braze welding are discussed in the article on Oxyacetylene Braze Welding starting on page 579 of this volume.

Equipment for Manual Torch Brazing

Manual torch brazing equipment is the same as, or very similar to, the equipment used for manual gas welding. A description of the design and use of this equipment, consisting of a gas supply, regulators, hoses and a gas torch is given on page 566 in the article on Gas Welding. Although most of the equipment described in that article can be used for torch brazing, tip selection and the technique of applying the flame to the workpieces differ. The safety precautions stressed in that article apply with equal emphasis to torch brazing.

Since the high heat intensity of the oxyacetylene flame, which is usually necessary for gas welding of steel, is not necessary for brazing, other gases such as natural gas, propane and various proprietary gases may be used in combination with oxygen or, where less heat can be tolerated, with air.

The high heat of oxyacetylene flames is often an advantage in reducing labor costs by shortening brazing time. Because of its relatively high cost, oxyacetylene heating is sometimes combined with air-propane or air – natural gas heating. For instance, in production brazing of massive steel assemblies, air-propane (or air – natural gas) is used to raise workpiece temperature to about 900 F before torch brazing with an oxyacetylene flame.

The particular oxy-fuel gas combination will determine the type of gas-supply equipment and regulator design, and also may affect the size of the hoses used and the design of the torch components. The sizes of the torch components, hoses, regulators and gas-supply system also must be appropriate to the general range of heating capacity required.

Equipment for manual torch brazing varies in cost from about $100 to $500, and usually includes attachments for general welding and cutting operations. When fuel gas in cylinders is used, manual equipment is usually portable; otherwise, torch mobility is limited by proximity of the fuel gas to the work. Accessories may include heating torches and tips, gas savers, flashback arresters and gas-fluxing equipment.

Manual torch brazing is usually done on a work table covered with fire-resistant cement board overlaid with refractory brick. A supply of these bricks should be available. They can be used to aid in the positioning of workpieces, and to reflect torch heat on the part being brazed. Reflected heat can also be used to preheat parts waiting to be brazed.

Asbestos screens and heat shields are used for protecting nonbrazing personnel and surrounding equipment from the heat of the torches, and for con-

serving torch heat that might otherwise be dissipated. Such screens also protect the assemblies from drafts.

All torch brazing, whether manual, mechanized or automatic, requires adequate ventilation in accordance with ANSI Standard Z49.1, *Safety in Welding and Cutting*, especially Section 7.4, *Work in Confined Spaces*, and Section 8, *Health Protection and Ventilation*. The sources of the most harmful fumes are the cadmium-bearing filler metals and the fluorine-containing fluxes. Ventilation must be provided in the manner, and to the extent, prescribed in the standard cited above. The level of the contaminant must not exceed established threshold limit values. The filler metals that contain cadmium are identified in the section on Filler Metals (see Table 1 on page 627), and the fluxes that contain fluorine compounds are discussed in the section on Fluxes, page 628, in this article.

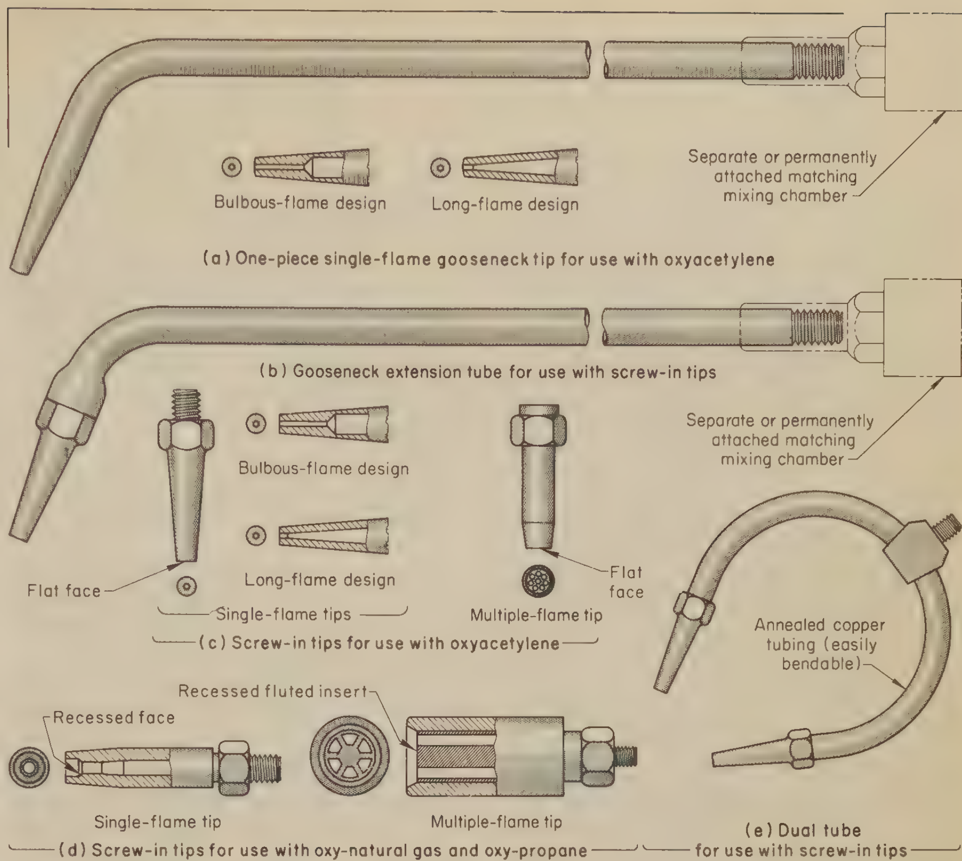
Major sources of safety rules and recommendations are listed in the section on Safety on page 578 in the article on Gas Welding.

Manual brazing torches designed for oxy-fuel gas consumption have three principal components: (*a*) the torch body, which serves as the handle and is equipped with needle valves to control the flow of oxygen and fuel gas; (*b*) a mixing head; and (*c*) a set of torch tips, which may be supplied with or without extension tubes. Essential details of these parts are shown in Fig. 3 and 4 in the article on Gas Welding (see pages 567 and 569).

Mixing-chamber design is of two basic types: equal-pressure and injector. Equal-pressure mixing chambers (also called medium-pressure and positive-pressure mixers) are used chiefly with acetylene, which can be supplied at pressures of about 1 to 15 psi; this type of mixing chamber cannot be used with fuel gas supplied at a pressure less than about 1 psi. (An equal-pressure mixing chamber is illustrated in Fig. 3 on page 567.)

Injector mixing chambers (see Fig. 4 on page 569) are used with fuel gases that are supplied at pressures less than about 1 psi or that require large quantities of oxygen. Injector mixing chambers, however, can also be used with higher-pressure fuel gases by throttling the fuel gas and oxygen by means of the torch inlet control valves. Individual adjustment is necessary for each tip size.

Because oxygen is readily available at high pressure, the injector mixing chamber is able to make use of the venturi principle by which a high-velocity jet of oxygen is made to draw or aspirate a low-pressure fuel gas. Injector mixing chambers are essential to the use of low-pressure generator acetylene and natural gas, which are often supplied at a pressure of about 1 psi or less. When using propane and certain proprietary gases that can be supplied at higher pressures, the injector mixing chamber is a convenient means of obtaining the higher oxygen-to-fuel gas ratios required. In torch brazing, volumetric oxygen-to-fuel gas ratios are approximately 1 to 1 for acetylene, about 2 to 1 for natural gas and about 4.5 to 1 for propane.



(a) Typical one-piece tip and tube extension commonly used for oxyacetylene brazing and welding. (b) Typical two-piece tip and tube assembly that permits quick replacement of tips. (c) and (d) Basic types of oxyacetylene, oxy-natural gas and oxy-propane screw-in tips. (e) Typical dual tip holder. All of the tip designs shown are available in a range of sizes, styles and capacities, and are used with complementary torch systems and gas settings.

Fig. 1. Tip designs used in manual torch brazing

The heating capacity of a torch is determined by the fuel-gas consumption rate, which in turn depends on the size of the tip orifice and the mixing chamber. The larger the diameter of the orifice, the greater the gas flow required to produce a proper flame and the greater the heating capacity. A given size of mixing chamber can usually supply the proper gas flow for a specific range of tip sizes. Selection of a tip size outside this range necessitates replacement of the mixing chamber with one of the appropriate size. The interchangeability of mixing chambers and of tips (including tip tube extensions and adapters) is limited and is prescribed by the manufacturer of the torch.

Torch tips for manual brazing differ according to the kind of fuel gas used, the tip-orifice diameter (heating capacity), and the style. Tips used with acetylene are usually faced off square across the orifice. Tips used with natural gas and propane are recessed or cupped at the orifice; otherwise, the lower flame-propagation rates of these gases might allow the flame to be blown away by the gas jet. In general, tips of both types are available in a range of orifice diameters designated by manufacturers' code numbers, on the basis of which recommended gas settings are supplied. Also available are multiple-flame tips that provide a broader flame coverage, useful in speeding the brazing operation. Fig. 1 shows several tip designs used in manual torch brazing.

Accessories. Heating torches that make use of multiple-flame tips of the type shown in Fig. 1 (c and d) are used for brazing with the lower-melting silver alloy filler metals. Because the flames are broader, heat transfer is more diffuse than with single-flame tips. These torches are frequently used in soldering, are less desirable for brazing with copper-alloy filler metals, and are not generally used for braze welding because of the time needed to reach operating temperatures. Torches equipped with multiple-flame tips are usually of a heavy-duty type and require larger-capacity mixers than those used with single-flame tips to handle higher gas flows. They may need larger gas-supply capacity.

Gas savers are used at brazing stations to conserve gas between brazing operations. The hoses are connected to dual valves actuated by a lever that also serves as a torch rest. In one type, the torch rest shuts off the gas completely, but an adjacent pilot flame permits instant re-ignition at the previous setting when the torch is lifted. Another type reduces the flame to a small size, which reverts to its former size when lifted from the rest.

Flashback arresters are used to prevent combustion or explosion from taking place in the hose if the flame, as a result of some malfunction, should burn back through the mixer and torch

handle. If not promptly stopped, flashbacks can result in injury to personnel and damage to equipment and property. The use and installation of flashback arresters are covered in ANSI Standard Z49.1.

The two principal types of flashback arrester are the mechanical check valve and the water-seal, or hydraulic back-pressure, valve. Check valves for oxygen and fuel gases supplied at about 1 psi or more consist of small threaded fittings that are inserted between the torch and the hoses to check back flow. They may also be installed between the hoses and the regulators or line gages. When used alone, check valves are not considered thoroughly reliable as flashback arresters, since flashbacks have been known to progress through them. Some check valves are capable of checking back pressures of less than 1 psi but tend to hinder very low inlet pressures.

Where large low-pressure volumes of acetylene or natural gas are distributed by pipeline, hydraulic arresters are used. Consisting of a tank partly filled with water, with an inlet pipe extending below water level and an outlet pipe terminating in the space above, these devices effectively stop the flashback. They are often used together with mechanical check valves. Utility companies often require such installations where they supply natural gas for use with oxygen. Flashback arresters are also used at the outlets of acetylene generators.

A third type of arrester consists of a closed cylinder of stainless steel wire mesh and operates on the principle of the Davy safety lamp. Installation is similar to that of the check valve.

Gas-fluxing equipment consists chiefly of a tank of liquid flux through which the fuel gas is bubbled to entrain the flux. This device is described in column 2, page 629 (see also Fig. 11).

Miscellaneous standard equipment includes: (*a*) tip cleaners, which are necessary for defouling tips, to maintain proper flame shape and to prevent tip overheating (one of the causes of backfires and flashbacks); (*b*) goggles, which are needed for eye protection; and (*c*) a set of wrenches, for proper tightening of tip, mixing-chamber hose and other connections.

Fixtures for Manual Torch Brazing

Holding devices include vises, clamps, pliers, tongs and special fixtures. Sometimes a simple holding fixture can be made to support a number of small assemblies. Ordinarily, it is preferable to make the assembly self-jigging, if possible. Where a fixture must be used, it should be constructed so that it will not interfere with the torch flame, the application of filler metal, or the operator's view. The fixture should be as light in weight as is practical, and should contact the assembly only where necessary.

Where a low heat sink is desired, point or line contact is preferable to contact over an area of surface. Ceramic points or contacts are available to minimize heat loss to fixtures.

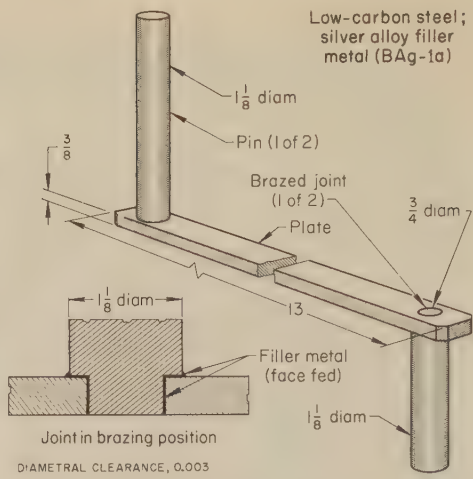


Fig. 2. Pin-and-plate assembly for which torch brazing was preferred because no fixture was needed (Example 574)

Conversely, where heat-sensitive components must be protected, larger surface contact and a conductive material, such as copper, can be used.

Asbestos shielding can be used to divert the heating effect of a torch and to protect a particular area. Shielding is used for this purpose when silver brazing small wires to avoid damage to insulation close to the joint.

The effect of thermal expansion of fixtures on joint clearance must also be considered, since the clearance must be effective at brazing temperature. In torch brazing, excessive heating of the fixture can usually be avoided and should be avoided, especially where complicated assemblies or high temperatures are involved. If parts are tightly clamped and rigid fixtures are overheated, the effect of expansion and contraction can result in overstressing of the joint and distortion of the part.

In the four examples that follow, simplicity of fixturing was one of the chief reasons for selecting torch brazing. In the first of these examples, no fixture was needed.

Example 574. Use of Torch Brazing To Eliminate the Need for a Fixture (Fig. 2)

Because the pins to be brazed were in opposite sides of the plate in the assembly shown in Fig. 2, some type of fixture would have been needed for almost any type of brazing except torch brazing. With torch brazing, one pin was brazed in place, the assembly was turned over and placed with that pin overhanging the edge of the worktable, and the other pin was brazed. The worktable was fire-resistant.

The pieces to be brazed (low-carbon steel) were cleaned in an alkaline solution, rinsed, and dried immediately before brazing. The ¾-in.-diam tenons and holes were fitted to close (0.003-in.) diametral clearance. The flux was a type 3A (see Table 2) containing an alkali borate-fluoride compound which first melted at 600 to 700 F and then became active at 1050 to 1100 F. The filler metal was silver alloy BAg-1a (see Table 1). Furnace or induction brazing was not practical because production lots were small and did not warrant the cost of a fixture.

Example 575. Use of Torch Brazing To Simplify Fixturing of a Complicated Assembly (Fig. 3)

An important reason for selecting torch brazing for assembling an air-inlet screen for a gas turbine was the simple fixture that could be used for holding the numerous parts in position. This fixture is shown in Fig. 3. All of the parts to be assembled — frame members, trunnion, and ribs — were made of 1020 steel. Before brazing, they were cleaned in a hot alkaline solution, rinsed, acid pickled, hot rinsed, and dried. The clean parts were then assembled in the fixture. Each joint was manually fluxed and torch brazed, using filler metal in wire form. After brazing, flux residue was removed by immersing the assembly in boiling water, the joints were visually inspected, and the fabricated screen was cadmium plated.

Brazing filler metal was silver alloy BAg-1a, which was well suited to torch brazing at a relatively low temperature (about 1200 F). Flux was type 3A in paste form.

Example 576. Use of Torch Brazing To Simplify Fixtures for a Tube-and-Flange Assembly (Fig. 4)

Close tolerances had to be maintained in assembling a bent tube to a support flange, as shown in Fig. 4. There was no seat in the flange to hold the 0.120/0.130-in. positioning dimension, and there were no locating features to keep the centerline of the tube and the centerline of the flange aligned within 0.010 in., as specified.

A fixture had to be built that would hold these and other dimensions while the assembly was being brazed. Because of the configuration of the part, the fixture had to be relatively large in comparison with the size of the joint to be brazed. It was considered impractical to build a number of duplicate fixtures for furnace brazing that would hold these assemblies within tolerances. A single fixture was built for manual torch brazing, as shown in Fig. 4.

Material of both tube and flange was cold drawn, low-carbon steel. The tube was 0.250-in.-OD seamless tube with a 0.035-in. wall. Diametral clearance between tube and

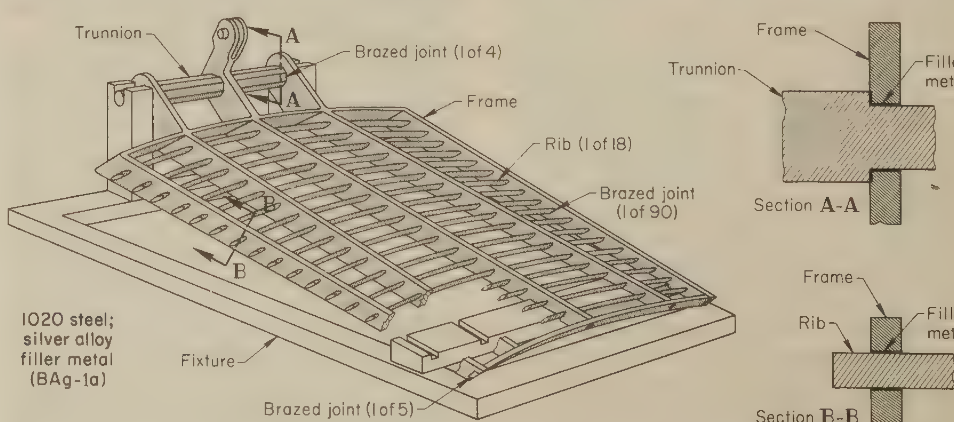

Fig. 3. Fixture for torch brazing gas turbine air-inlet screen, the assembled screen, and location of brazed joints (Example 575)

flange varied from 0.002 to 0.013 in. The parts were vapor degreased before application of a type 3A paste flux. After fixturing, the parts were brazed using a face-fed BAg-1a wire, 0.031 in. in diameter. After brazing, the assemblies were cleaned for nickel plating. Production rate was 30 pieces per hour.

Arc welding was rejected as a joining method because of possible burn-through and poor appearance. Soldering was not used because the joints would not have been strong enough.

Example 577. Use of Torch Brazing and a Simple Fixture To Meet Airtightness and Dimensional Requirements of a Tubing Assembly (Fig. 5)

The low-carbon steel tube assembly shown in Fig. 5 was manufactured in quantities of about 15,000 units annually. It was essential that the two short pieces of tubing be parallel within ±0.005 in.; that the cross-sectional area on the inside of the long tube not be decreased by more than 25% by excess filler metal; that all joints be airtight (withstand 10 psi minimum); and that a 0.170-in.-diam gage plug fit freely through the short tubes into the long tube after brazing.

The brazing fixture consisted of a V-grooved bar for the long tube with two V-grooved bars at 90° for the short tubes, two locating plugs that were inserted through the short tubes into the holes in the long tube, and toggle clamps to hold the assembly in alignment. The locating plugs were removed after the parts were clamped in place.

Joint preparation consisted of (a) drilling two holes, 0.188 ± 0.002 in. in diameter, in the long tube, (b) milling the mating ends of the short tubes to fit saddlewise over the holes in the long tube (Fig. 5) and (c) degreasing the parts in a water-soluble cleaner, and rinsing in cold water and then in hot water to speed drying. The joints were brushed with a paste flux that corresponded to an AWS type 4, and which proved to be an acceptable alternate to type 3A in this application.

Joint clearances, after fixturing, varied from 0.0005 to 0.003 in. The joints were heated by manually passing the neutral flame of the torch around the joint to heat the area to the brazing temperature, which was approximately 1200 F. The wire of BAg-1 silver alloy filler metal was then face fed at the top surface of the joint, with the assembly positioned as shown in Fig. 5 (Section A-A), and flowed around to complete the joint.

Further details are given in the table accompanying Fig. 5.

Equipment for Machine Torch Brazing

Various mechanical devices are used to perform repetitive torch brazing operations. Machines have been built for fixturing, fluxing, heating, face feeding of filler metal, forced cooling, hardening and other operations. Flowmeters and manometers are often used to monitor and control gas ratios where large gas volumes are involved. However, it is not always possible or desirable to mechanize all torch brazing operations. Workpiece configuration, joint design and accessibility, or other factors will determine whether some operations are done best by hand or by machine, even though large production quantities are involved. Machine torch brazing is the term used for operations that are partly manual, partly mechanical.

In principle, motion can be imparted to the workpiece or to the brazing equipment, or both. Usually, though, the workpiece, at a certain stage of the operation, is moved past one or more stations where a brazing function is performed manually or by machine. The two most frequently used means of movement are the conveyor belt and the turntable. Brazing operations can be set up for either mode of travel.

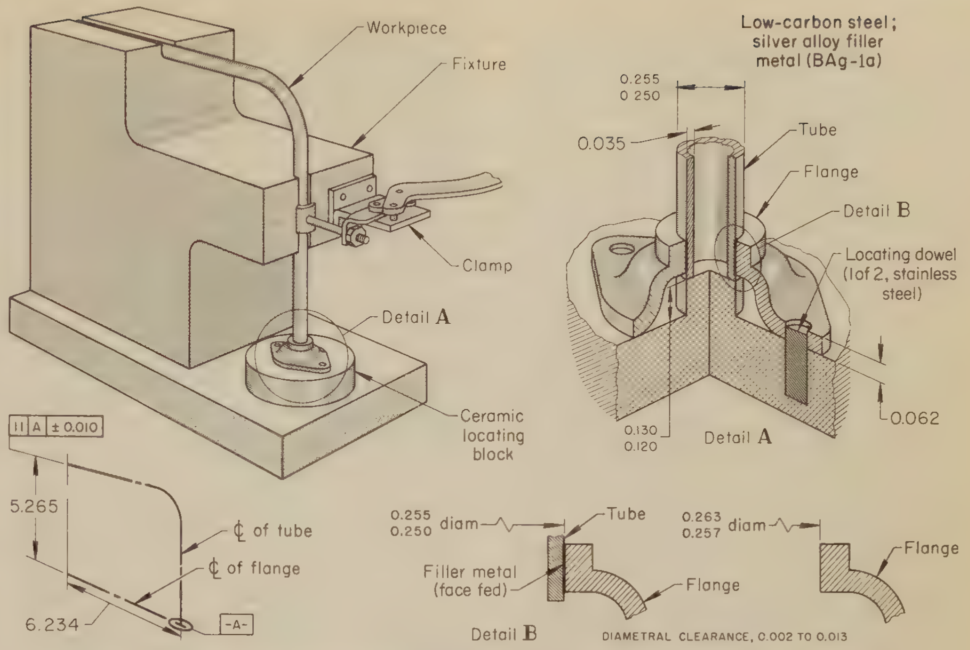

Fig. 4. Tube-and-flange assembly, showing fixture used for manual torch brazing (Example 576)

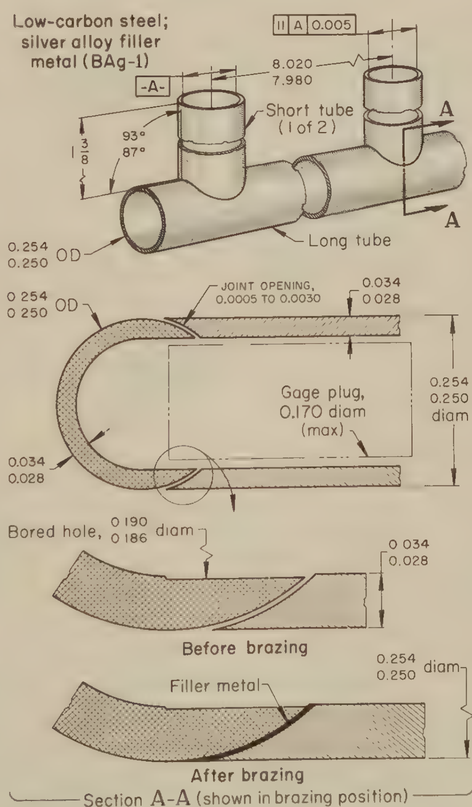
Heating is the operation most often mechanized, since it is relatively simple to move workpieces past fixed torches or burners with controlled timing. Manual operations may include fluxing, filler-metal preplacement and fit-up.

Conveyor belts are often used to carry the workpieces under a series of fixed burners and then through an air blast or water jet for cooling. In this type of setup, joint assembly, fluxing, and filler-metal addition are usually done manually before the part is placed on the conveyor.

For instance, in fabricating air-conditioner cooling coils (in this case, the base metal was copper) 18 return bends had to be brazed to the flared, open ends of the U-tubes, which had been fitted with cooling fins. The return bends were cut from tubing, formed and mechanically fitted with a preform of filler-metal wire. They were then manually fitted into the U-tubes and the assembly was loaded on hangers on a continuous conveyor belt.

On the conveyor, the assembly first was purged with natural gas flowing from a small tube inserted in one end. The assembly was then carried under two sets of compressed air – natural gas, radiant-type burners, the first set for initial heating, and the second for melting and completing the flow of filler metal. Flux was applied by gas fluxing through the burners. In addition to the conveyor system, this setup incorporated a combustion-control pumping and metering machine capable of supplying several thousand cubic feet of proportionately mixed gas per hour. Gas-fluxing equipment (see "Gas Fluxing", page 629), and a calcium chloride drying tank, were installed as part of the gas supply system. No difficulty was experienced in timing the manual operations and the conveyor speed to machine-torch braze approximately 180 air-conditioner cooling assemblies per hour.



Torch type	Oxyacetylene
Flame type	Neutral
Tip-orifice diameter	0.0380 in.
Filler metal	0.031-in. wire, BAg-1
Flux	AWS type 4
Production rate	30 assemblies (60 joints) per hour

Fig. 5. Tubing assembly that met airtightness requirements and close dimensional tolerances after brazing (Example 577)

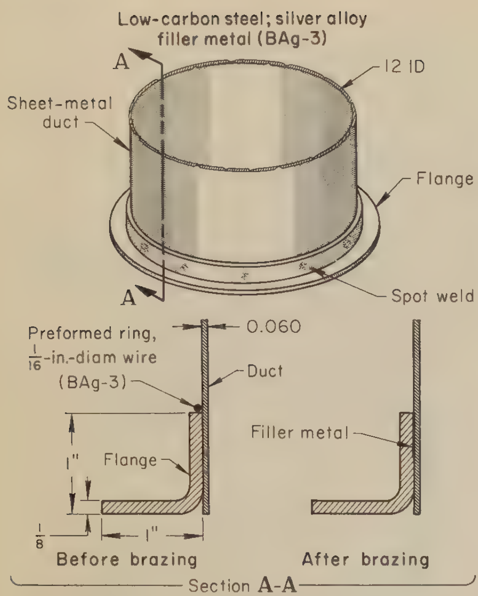


Fig. 6. Air duct on which a flange was sealed by brazing in a turntable setup (Example 578)

Turntables provide a means for any degree of automation. A circular table is fitted with a series of duplicate holding fixtures equally spaced on the rim. The number of fixtures equals the number of operating stations that are located in fixed positions around the outside of the table. At any station, the operation may be manual, partly manual and partly mechanical, or completely mechanical; the choice is determined by the nature of the workpiece. For instance, devices are built to face feed liquid, paste or powder flux at one station and wire filler metal at another, or an applicator can be used to face feed a paste mixture of powder filler metal and flux.

The joint design of the workpiece must be amenable to face feeding from one or more fixed-point sources. Even if the joint area is not so large or so inaccessible as to require prefluxing or filler-metal preplacement, there must be at least a small area on the joint where the filler metal can rest momentarily. Complex joint configurations usually necessitate hand feeding.

Heating from fixed stations presents few difficulties, because single or multiple burners can be mounted at one or more stations and connected to a common gas supply. In the more complicated torch brazing machines, the dwell time at each station is determined by the time taken for the filler-metal application; the total heating time is obtained by adding the number of heating stations needed to complete the particular thermal cycle. Air-cooling and water-cooling stations are added to obtain desired cooling rates. In some installations, turntable indexing and rotation are controlled by electronic timers.

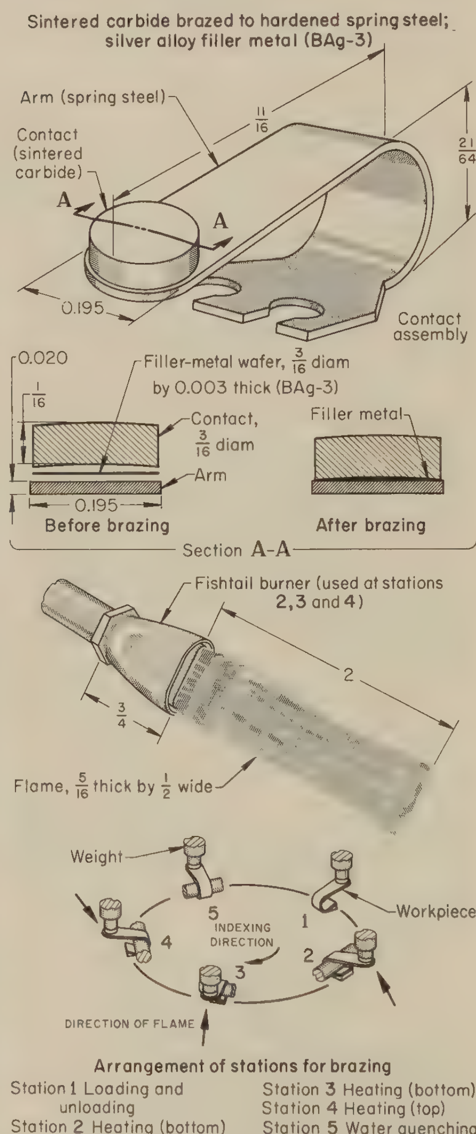
The three examples that follow describe applications in which simple turntables were used to rotate the assemblies past several heating burners to achieve required production rates at relatively low capital investment. In each application, assembly and fluxing were done manually.

Example 578. Use of a Turntable To Mechanize Heating of a Joint (Fig. 6)

Sheet-metal ducts of a closed-air system were joined by bolting companion angle-iron rings that had been cold formed and welded, and then resistance spot welded to the ducts, as shown in Fig. 6. A low-cost method was needed to seal the space between the 1-by-1-by-⅛-in. steel angle rings and the 16-gage (0.060-in.) cold rolled steel ducts. The following simple brazing operation fulfilled the requirement.

A brazing machine consisting of a turntable and six propane burners mounted around a third of its periphery was constructed at a cost of $250. Only the tips of the burners were newly purchased; they were mounted on the supply pipes.

Brazing flux (type 3A) was applied to the joint and a preformed ring of 1/16-in.-diam, BAg-3 silver alloy brazing wire was positioned as shown in Fig. 6.



Fuel system .....Premixed natural gas and air piped to each burner; 4 in. water column pressure at burner
Burner type ......Fishtail; flame 5/16 in. thick, ½ in. wide, 2 in. long; 1280 Btu per hour
Filler metal ....0.003-in.-thick by 3/16-in.-diam, BAg-3
Flux ....AWS type 3A
Production rate ....300 assemblies per hour

Fig. 7. Contact assembly that was brazed and quenched in a turntable setup (Example 579)

The assembly was then placed on the turntable and rotated past the burners, with the flames turned low, to dry out the flux. When the joint was dry, the burners were turned up to activate the flux and melt the filler metal. Sufficient flow was obtained to seal the joint.

Torch brazing was the most economical of the brazing methods that could have been used. Resistance heaters, instead of gas burners, were briefly considered, but the cost of tooling would have been about $2500. Induction brazing equipment would have cost about $20,000, and furnace brazing equipment would have cost about $25,000. The small quantity of assemblies required could not justify these costs.

Example 579. Mechanized Heating and Cooling of a Joint on a Five-Station Turntable (Fig. 7)

The contact assembly shown in Fig. 7, which consisted of a spring steel arm and a sintered carbide contact, was brazed on a turntable using burners supplied with premixed air – natural gas. Fluxing and loading were done by hand; the remaining steps were automatic, including the cooling operation. The production rate was 300 assemblies per hour, and the normal manufacturing lot was 100,000 assemblies.

The spring steel arm was supplied in the hardened condition and with a bright finish. It was vapor degreased before assembly. The parts were held by tweezers and dipped in AWS type 3A liquid flux and loaded on the turntable with a wafer of BAg-3 silver alloy filler metal, 3/16 in. in diameter (the diameter of the carbide tip) and 0.003 in. thick, between them. A weight on the top of the carbide tip held the parts in position during brazing.

Three fishtail burners, with the flat "tail" in the horizontal position, were used to heat the assemblies. Burners at stations 2 and 3 heated the assembly on the underside of the joint and the burner at station 4 applied heat to the joint on the top side to melt and flow the filler metal. Water-spray cooling followed at station 5. The hardness of the arm was not changed so as to affect its function as a spring.

Example 580. Machine Torch Brazing of a Printing-Machine Part on an Eight-Station Turntable (Fig. 8)

Magnet armatures, of the type shown in Fig. 8, were used as the striking members of a printing machine. The 0.040-in.-thick striker blade was made of high-carbon (0.65 to 0.85% C) spring steel so that the outer end, which engaged a linkage at 250 times a minute, could be locally hardened to resist wear. A brazed joint was required between the blade and the 5/32-in.-thick armature, made of 2½% silicon steel.

Conventional furnace brazing with copper filler metal was not suitable for this operation because (*a*) the slotted joint design did not lend itself to the tight fit required for copper brazing, (*b*) the high brazing temperature (2050 F) would coarsen the grain structure of the high-carbon steel blade, and (*c*) the furnace atmosphere needed to prevent decarburization of the blade was expensive.

Brazing the assemblies on a turntable using a silver alloy filler metal and either induction or flame heating would provide the desired production rate, while avoiding the objections to furnace brazing. Machine torch brazing was selected because the capital investment was lower and a metal fixture, cooled by circulating water, could be used to maintain the close dimensional tolerances required over long production runs. A timer-controlled eight-station brazing turntable was built (Fig. 8) to perform all operations except fluxing, assembling and loading, which were done manually. The burners were supplied with low-cost air – natural gas for heating.

The operating sequence was as follows:

Station 1. The operator dipped the joint end of a blade in type 3B paste flux, assembled it with an armature and loaded the assembly in the fixture.

Stations 2, 3 and 4. The joint was preheated by rotating it past burners clamped to brackets, one at each of the three stations.

Station 5. A fourth burner brought the joint to the melting temperature of the BAg-1 filler-metal wire, which was automatically face fed to the joint. A microswitch probe detected the assembly and caused the wire feeder to slide into position, face-feed 1 in. of 0.032-in.-diam wire (which melted on the joint), and retract.

Station 6. Filler metal was brought to brazing temperature by a fifth burner and flowed through the joint.

Station 7. The assembly and fixture were cooled by an air blast.

Station 8. A stationary trip pin unclamped the fixture, releasing the assembly, which was then ejected by an air-actuated plunger. The fixture was cooled by a water spray.

Production rate averaged 230 assemblies per hour. After brazing, the striker ends of the blades were hardened in a separate operation. Induction heating was used for this operation because it provided closer control over the dimension being hardened and allowed an oil quench.

Equipment for Automatic Torch Brazing

Automatic torch brazing equipment eliminates the human element from the brazing operation, except for loading and unloading of the machine. The advantages are: (*a*) high production rate, (*b*) uniform joint quality and (*c*) economy in the use of gases, flux and filler metal. Automatic torch brazing is applicable to a wide variety of small parts. Large, extended or massive workpieces present the usual problems of heat control, filler-metal flow and distortion. For such pieces (a filler pipe joined to an automotive gasoline tank is an example), soldering is usually selected for the joining method (if the strength is satisfactory), rather than brazing.

The machines and other equipment used in automatic torch brazing are basically the same as those described in the previous section on machine torch brazing. The use of burners rather than torches usually requires the installation of flowmeters and manometers for accurate flame control. An automatic setup lends itself more easily to multiple-joint or multiple-part brazing. Production rates are much higher.

Two types of face-feeding machine have made automatic torch brazing possible. They are the wire feeder and the paste feeder. Both machines are of the fixed-station type and are used in conjunction with a work-fixtured turntable or conveyor belt. Both are controlled by timers and are activated by a probe or limit microswitch that determines whether the approaching fixture is loaded. Various combinations of fluxing, filler-metal feeding and heating sequences are possible.

Wire Feeders. One type of wire feeder incorporates a double slide. The first slide advances the gas torches or burners into position. After a preset interval, the second slide advances wire-guide tips to the joint, and filler metal is fed, melting off on contact. When the correct amount of filler metal has been melted off, the wire is quickly retracted to prevent balling at the end. Heating is continued until the filler metal is distributed through the joint, and the torches or burners are then retracted.

In this system, flux is applied in either liquid or paste form at a previous station and gas fluxing is done through the torch or burner flames. The assembly is cooled by air or water at following stations.

The most critical part of the operation is the setting of the wire-feed rate to coincide with the wire melting rate; lack of coordination results in either an underfed joint or waste of filler metal (usually silver alloy). Cycle timing, slide motion and wire-feed rate are individually controlled by an electronic timing circuit.

Paste feeders apply a mixture of flux and powder filler metal to the joint or joints to be brazed. The paste is contained in a cylinder equipped with a piston to eject the paste through a nozzle. One or more cylinders are mounted on a single slide that enables the applicator to be positioned at the desired points of deposition.

The operating sequence, which is triggered by a microswitch striking the fixtured workpiece, consists in sliding the applicator into position, depositing a predetermined quantity of paste, and retracting. The workpiece is then moved through a series of burner stations where the flux is dried, melted and activated, and the filler metal is finally melted and distributed through the joint. Cycle timing, slide motion and paste feeding are controlled by electronic timing circuits. As in other automatic machines, stations are set up for loading, cooling and unloading. This system can also make use of gas fluxing, when it is required to keep the workpiece clean.

The following example describes the equipment used and the operations performed on an appliance part that required a high production rate.

Example 581. Automatic Torch Brazing of an Appliance Part on a 12-Station Turntable (Fig. 9)

A machine for high-production torch brazing of the joint between the low-carbon steel blades and shaft of an electric food beater required only manual loading. All other operations were controlled automatically, including ejection from the brazing fixture. The assembly, together with joint details, is shown in Fig. 9. The formed blades were fixed at one end of the shaft by riveting over a through-pin integral with the shaft. The four ends of the blades were notched to form a mitered cross, which fit precisely into the 0.045-in.-wide by 1/16-in.-deep annular groove cut in the shaft. Squeezing the blades together produced the desired joint configuration.

The machine consisted of a 12-station turntable with a station dwell time of 3.55 sec and a between-station indexing time of 1.25 sec, producing 750 assemblies per hour. The braze was made using a face-fed paste of BAg-1 silver alloy filler metal and flux. Heating was done with air – natural gas burners, with added gas fluxing to keep the assembly clean. Figure 9 shows the general arrangement of stations around the turntable and identifies the operations performed at each station. Turntable rotation was controlled by a timer that was set for station dwell time; indexing time was a machine constant. The following sequence describes the operations performed and the equipment used at each station:

Station 1, Loading. This station was equipped with an external loading device that slipped the beater blades into the circular opening in the locator arm of the holding fixture on the turntable. The loading device consisted of a cup-shaped die with four equally spaced slots to hold the beater blades in position for brazing and a hole in the center for the beater shaft. The die was fixed on a crossbar supported by two spring-loaded shafts, on which rode a sliding crossbar attached to a loading pin that was actuated by an air cylinder, as shown in Fig. 9.

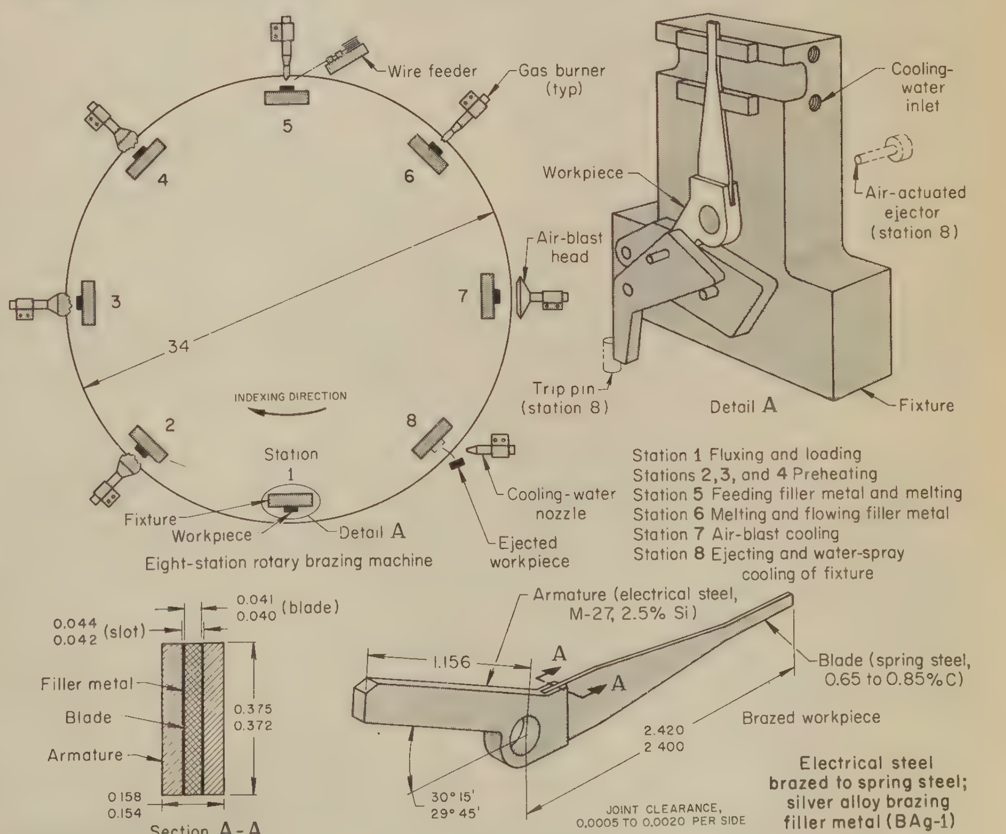


Fig. 8. Armature assembly and a schematic representation of the turntable machine used to braze 230 of the assemblies per hour (Example 580)

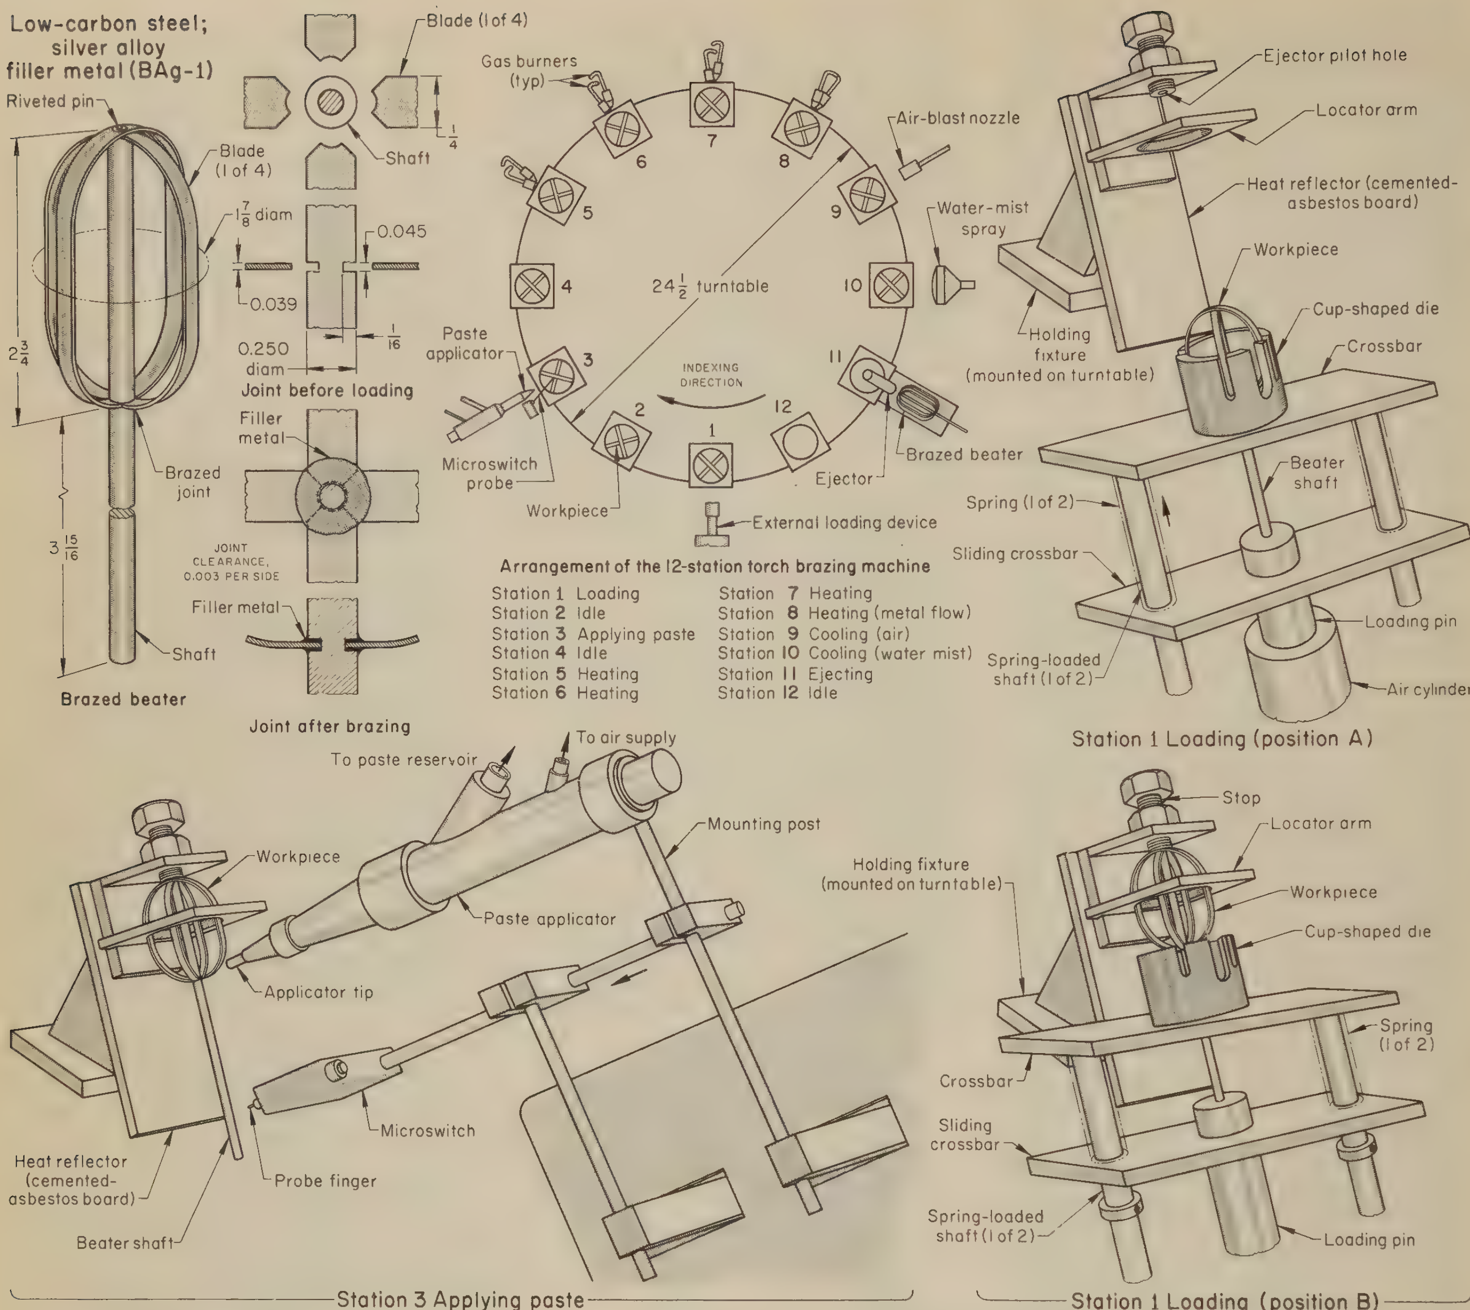

(Top, left) Food beater showing details of the joint before loading and after brazing. (Top, center) Schematic view of the turntable showing arrangement of the equipment used at 9 of the 12 stations and the operating sequence. (Right) Two views of the loading operation. In position A, the workpiece is fitted in the joint-forming die preparatory to loading; in position B, the workpiece is loaded into the locator arm of the holding fixture and the loading device has begun to retract. (Bottom, left) Paste applicator and microswitch probe that detected the presence of the workpiece and initiated the paste-feeding cycle. The workpiece was manually fitted in the loading die.

Fig. 9. Workpiece and the equipment and operating features of an automatic torch brazing machine of the paste feeder type (Example 581)

As the assembly was manually loaded into the die, the beater blades were squeezed together, positioning the ends in the joint. By pressing a button-switch, the operator caused the entire loading device to move upward. The spring-loaded shafts were end-stopped part way through the loading operation, but the sliding crossbar and loading pin continued to the end of the stroke, pushing the beater shaft until the four blades were engaged in the locator arm. When the loading device retracted, the machine indexed to the next station.

The turntable fixture, in addition to supporting the locator arm, had a bolt-and-locknut vertical stop with a hole through the center to permit entry of an ejector pin (station 11). A cemented-asbestos board over the fixture support served as a heat reflector. Fixture design is shown in Fig. 9.

Station 2, Idle. This station was idle to give the operator freedom from interference with the sizable apparatus at station 3.

Station 3, Paste Feeding. This station was equipped with a device consisting of a paste applicator and a microswitch, post-mounted on a slide, an air-pressurized paste reservoir, connected to the applicator by a plastic tube, and an air-supply tube to actuate the applicator piston. Figure 9 shows the general arrangement of these parts. This station also had a separate control panel with (*a*) a paste-pressure control knob set for 17 psi, (*b*) a meter indicating applicator operating pressure (40 psi), (*c*) a timer that controlled the paste-feed cycle, and (*d*) a cycle counter.

When the slide moved the applicator nozzle into position over the joint to be brazed, the probe finger of the microswitch was deflected by the workpiece. This closed the switch and started the timed cycle in which the piston ejected the correct amount of paste onto the joint. Approximately one ounce of paste supplied 200 parts.

Station 4, Idle. This station was idle to separate the paste-feeding equipment from the heat of the torches.

Stations 5 to 8, Heating. Each of these four stations had two air – natural gas burners with tips mounted on bendable copper tubing. In stations 5, 6 and 7, the tips directed the gas flames onto the beater shaft above and below the workpiece joint, for progressive heating. At station 8, the flames were directed so as to converge on the joint to complete the melting and obtain flow of the filler metal.

Air and natural gas were pumped, metered and mixed in a combustion control unit mounted in the base of the machine. The ratio of air to natural gas was 9 to 1. The supply of natural gas was monitored by a flowmeter; a manometer indicated the pressure of the gas mixture in the burners.

Station 9, Cooling. This station was fitted with an air-blast nozzle for cooling the workpiece.

Station 10, Cooling. The workpiece was further cooled with a water-mist spray.

Station 11, Ejection. When a fixture was indexed at this station, an air piston moved a pin down through the hole in the vertical stop, ejecting the part into a chute and out the side of the machine into a bin.

Station 12, Idle. This station was idle to give the operator freedom from interference with the collection bin.

After flux removal, the assemblies were chromium plated.

The main control panel for the machine had the following controls: emergency stop button, start button, a light signaling that paste was applied, a turntable-cycle on-off switch, an applicator on-off switch, and an on-off switch for the gas-combustion control unit.

Success with this machine indicated that the operator could easily load two beaters at one time, using both hands. Accordingly, a machine with 12 duplex stations was installed. Although larger and more complex than the machine described above, the equipment and operation were essentially the same. The new machine brazed 1400 to 1500 assemblies per hour.

Filler Metals

Silver brazing alloys and copper-zinc brazing alloys are the filler metals used in torch brazing of low-carbon and low-alloy steels. The product forms, nominal compositions, and the melting and brazing temperature ranges of the filler metals most frequently used are given in Table 1.

Choice of filler-metal form depends mainly on the joint design and the method of assembly. The amount of filler metal used can be controlled accurately by the use of preformed shapes bent from wire or blanked from strip. These can be preplaced in and around joints of various designs, in a manner that will enhance flow and complete filling of the joint.

Filler metal in powder form is often used, although if it is used on the exterior of the joint some provision must be made to hold it in place. One method is first to brush the joint with paste flux and then to dust the filler-metal powder lightly onto the flux while it is still wet. Another method is to mix the powder with flux and a binder to form a paste, which is then applied by brushing or face feeding through an applicator. Rod and wire can be manually face fed; automatic wire face-feeding equipment and paste-applying equipment are also available, as described earlier.

Silver Alloy Filler Metals

Silver alloys BAg-1 through 7 are used for torch brazing most types of steel to themselves or to other metals, except aluminum and magnesium, and are available in several product forms. (Alloys BAg-8 through 19 are used chiefly in furnace brazing.)

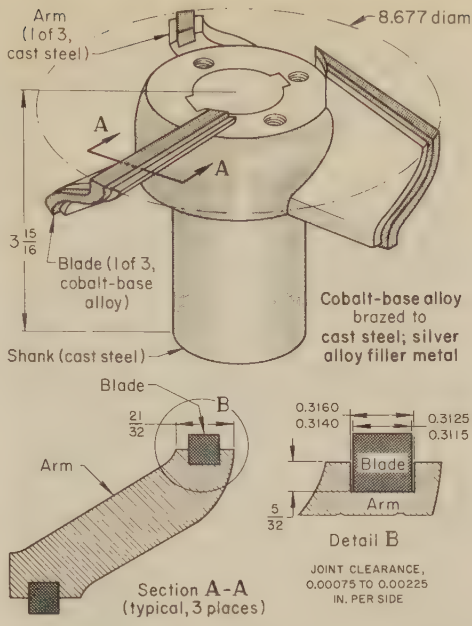

Fig. 10. Cutting impeller, with inserted blades of cobalt-base alloy, that performed satisfactorily in service only after joint clearances were controlled in brazing (Example 582)

The most frequently used alloys of the group shown in Table 1 are BAg-1, 1a and 3; the first two are outstanding for high fluidity, low melting temperature and narrow melting range. BAg-1 is much preferred for fast-cycle torch brazing, especially for automatic torch brazing with low-cost air – natural gas heating. The BAg-3 alloy contains nickel for improved wettability when brazing tungsten carbide (tool tips), and has lower fluidity for bridging larger joint clearances. BAg-2 and 2a are similar to 1 and 1a but contain less silver and are therefore cheaper; they also have a somewhat wider melting range.

These filler metals contain cadmium, which is added to depress the melting range and to improve flow properties. Because cadmium fumes are toxic, industrial brazing installations must be provided with adequate ventilation as described in the section on Equipment for Manual Torch Brazing. Federal regulations also stipulate that cadmium-bearing filler metals and their toxic properties be identified by a suitable warning label, because of the possibility of home and farm applications.

BAg-4 through 7 are cadmium free, a requirement for some food-processing applications. BAg-4, containing some nickel and being freer flowing than BAg-3, is used for brazing carbide tool tips. BAg-5 and 6 are widely used on electrical and food equipment. The melting range of BAg-7 is the lowest and narrowest in temperature of the cadmium-free alloys; containing tin, BAg-7 produces a white color that matches steel, in contrast to the somewhat yellowish color produced by the other silver alloys.

Joint clearances of 0.002 to 0.005 in. are often recommended for silver alloy filler metals. However, the clearances used in torch brazing vary considerably, as is seen by comparing Examples 576, 577, 580, 582, 584 and 586 in this article. Because joint clearance is a factor in capillary flow, too little or too much clearance affects filler-metal distribution, which affects joint strength (see page 607 in Furnace Brazing).

Maintaining consistently proper clearances is particularly important in automatic face-feeding operations. Some latitude is possible in face-fed manual torch brazing, especially if joint strength is not critical.

Where joint strength is critical, a poor fit, even if not apparent in the completed joint, is likely to show up in service. In the example that follows, the brazed joint was subjected in service to shock and fatigue loads, but no systematic provision for control of joint clearance was made until failures were reported.

Example 582. Specification of Clearance To Improve Reliability of Silver Brazed Joints (Fig. 10)

The cutting impeller shown in Fig. 10 was composed of a cast steel body consisting of a shank and three arms, each of which contained blades made of a cobalt-base alloy (30 Cr, 18.5 W, 3.5 Ni, 2.5 Fe, 2.0 C, 6.0 other). The blades were cut from 5⁄16-in. square wire, inserted into grooves in the arms, and joined to the arms by torch brazing.

Originally, the grooves were machined 5⁄16 in. wide by 5⁄32 in. deep with no specification on tolerance. During assembly, the blades were ground and fitted by trial and error, and held in position by movable C-clamps. Joint clearance was left to the judgment of the operator.

A silver alloy and a proprietary flux were selected for manual brazing with an oxyacetylene torch. The silver alloy filler metal was a cadmium-free, low-melting (1130 F) type with whitish color, similar to BAg-7. During heating, the torch flame

Table 2. Flux Types Commonly Used in Torch Brazing of Low-Carbon and Low-Alloy Steels

AWS type	Useful temperature range, F	Principal constituents	Available forms	Applicable filler metals
3A	1050 to 1600	Boric acid; borates; fluorides; fluoborates; wetting agent	Powder; paste; liquid	BAg-1 through 7
3B	1350 to 2100	Boric acid; borates; fluorides; fluoborates; wetting agent	Powder; paste; liquid	BAg-1 through 7, RBCuZn
5	1400 to 2200	Borax; boric acid; borates; wetting agent	Powder; paste; liquid	RBCuZn

was applied to the steel body only, until brazing temperature was reached. A 1/16-in.-diam wire of filler metal was then fed and melted into the joint, the clamps being moved as necessary. Production time for the three arms was ½ hr. Visual inspection indicated no problems. The assemblies were washed in water, wire brushed and ground to size.

In service, however, the blades often came loose and subsequently broke. Investigation showed a large variation in joint clearance. The blade material was then obtained ground to size, 0.3120 ± 0.0005 in. square. Dimensions of the groove were changed to the size and tolerance shown in Fig. 10, which gave a total clearance of 0.0015 to 0.0045 in. at room temperature. Since that change, no service failures have been reported.

Copper-Zinc Filler Metals

Copper-zinc filler metals are extensively used in manual torch brazing and braze welding of low-carbon and low-alloy steels. They can also be used to join nickel-base and copper-nickel alloys to themselves or to steel, where corrosion resistance is not required. Table 1 gives the nominal composition and melting characteristics of four copper-zinc alloys used as filler metals. The two RB types are classified for braze welding and brazing; the two R types for braze welding only. The R types are included in Table 1 to clarify a distinction among the four standard copper-zinc filler metals that is often overlooked; only the two RB types are used in torch brazing, but all four copper-zinc filler metals can be used in braze welding.

Copper-zinc filler metals have higher melting and brazing temperatures than silver brazing alloys. However, overheating must be avoided, because of their high zinc content. When the alloys are overheated, zinc vaporizes ("fumes"), causing voids in the joint. RBCuZn-A, often called naval brass or bronze, produces some zinc fuming and is brassy in color. RBCuZn-D, containing 10% nickel, is often called nickel silver, because of its whitish color, although it contains no silver. RBCuZn-D is often selected for its low fuming and high strength, as well as for its good color match with steel. Because of its high brazing temperature, it is possible, when brazing some heat treatable steels, to combine brazing with heating for hardening. Chromium-molybdenum steels have been brazed and heat treated in this manner. Both RB types of filler metal have a relatively narrow melting range. When used for torch brazing, joint clearances of 0.002 to 0.005 in. are recommended. These filler metals are also available as pastes for automatic torch brazing.

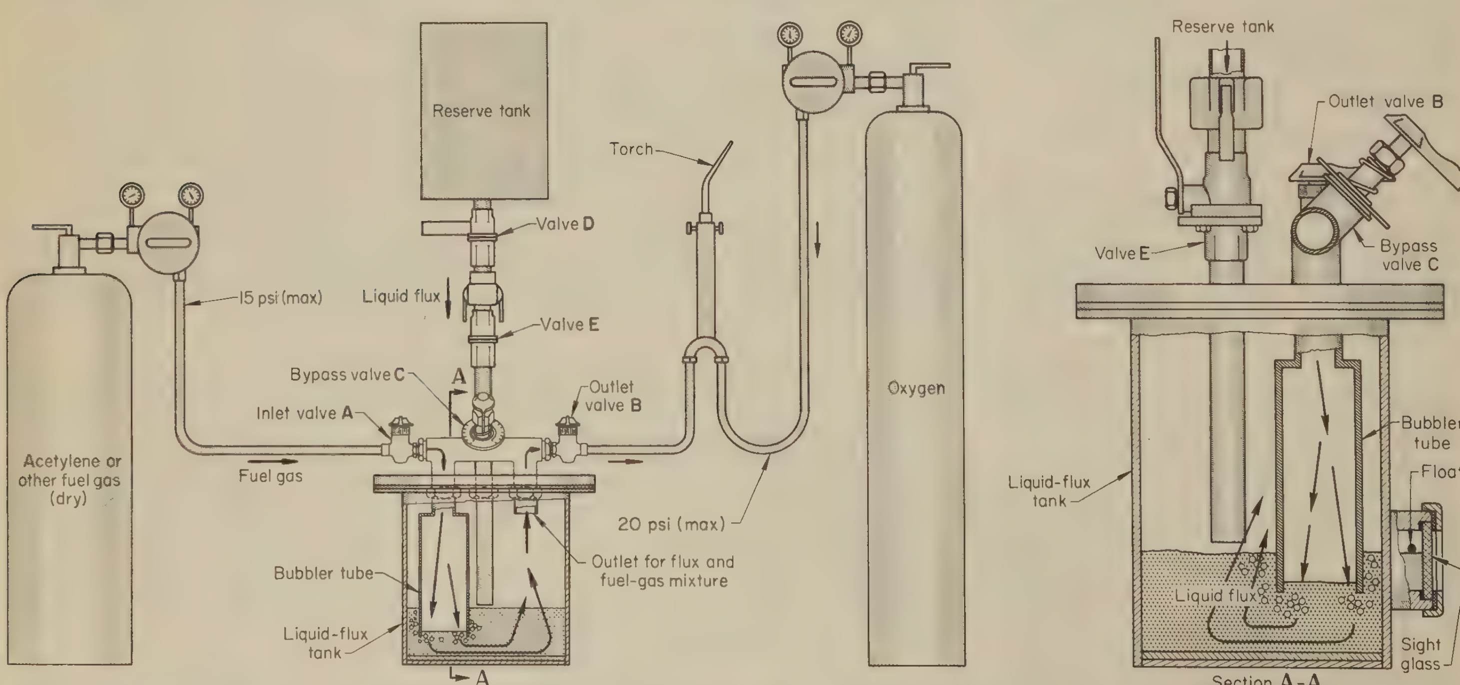
Fluxes

Surface oxide films inhibit the wetting of the base metal by the filler metal and therefore the capillary flow of the filler metal in the joint; they also prevent the formation of a true metal-to-metal braze bond. Fluxes must have sufficient chemical and physical activity to reduce or dissolve the thin surface films without attacking the base metal severely. They are not made to dissolve greases or dirt. For these reasons, fluxes are not intended to serve as a substitute for prebraze cleaning or for removal of heavy oxide films. The chemical reactivity of a flux with the oxides and other compounds encountered on the surface of the base metal varies according to the stability of the compounds.

Because the heat of brazing accelerates the formation of films, such as oxides, fluxes must also melt and flow freely over joint surfaces to shield the metal from the atmosphere under the torch brazing conditions. In addition, because different filler metals vary as to melting range and brazing temperature, fluxes must maintain their stability and effectiveness throughout the brazing temperature range of the filler metal being used.

Finally, the density, viscosity, and surface tension of the molten flux must be low enough to enable the molten filler metal to replace the flux on the joint surfaces by capillary flow. It is also important that fluxes be easy to remove after brazing, preferably by washing in hot water.

Flux Constituents. Brazing fluxes are available chiefly as proprietary formulations; there are no standard specifications, such as those for filler metals. A general list of the compounds used in brazing fluxes is given below; of these, the boron and fluorine compounds are the active deoxidizing constituents used in fluxes for the torch brazing of steel.



Fuel gas flows through the inlet valve A into the liquid-flux tank, where it bubbles through the flux, entrains some of it and carries it through the outlet valve B to the torch. The bypass valve C controls the proportion of fuel gas entering the bubble chamber to provide rich or lean fluxing mixtures. Valves D and E are for refilling the liquid-flux tank and for removing the reserve tank for remote filling without stopping the operation. Joints must be sealed to prevent moisture pickup from air, which would cause precipitation of flux and clogging of lines.

Fig. 11. Gas fluxing hook-up for a manual brazing station

Fused borax is a high-melting material that is active at high temperatures. It is seldom used in low-melting brazing fluxes.

Borates melt at 1400 F or higher. They have moderately high viscosity and must be used with other constitutents. They are potent oxide solvents and protect against oxidation for long periods.

Fluorides react readily with most metallic oxides at high temperatures, and are used in fluxes as cleaning agents. They are especially useful in counteracting refractory oxides, such as chromium oxide and aluminum oxide. They also increase the fluidity of molten borates.

Chlorides function in much the same manner as fluorides, but at a lower temperature. They must be used carefully, because at high temperatures they may oxidize the work metal. Chlorides are used to depress the melting temperature of fluoride-base fluxes, and are useful in brazing aluminum.

Fluoborates react in somewhat the same way as borates, but they do not give as long-lasting protection. They flow better in the molten state than the straight borates, and have superior oxide-dissolving properties. Fluoborates are used in combination with borates and alkaline compounds such as carbonates.

Fluosilicaborates have a somewhat higher melting range than fluoborates. They cover and adhere to surfaces well, but they are more limited in use than fluoborates because of their high melting point.

Hydroxides of sodium and potassium absorb moisture from the air, and therefore are used in fluxes for special applications only. Even small amounts in other fluxing agents can cause difficulty and limit storage life in humid environments. They raise the useful working temperature of fluxes and are used in fluxes for brazing molybdenum-bearing tool steels.

Boric acid is used in the conventional and in the calcined form. The calcined form has a somewhat higher melting point. Both forms promote friability to help facilitate the removal of the glasslike flux residue that remains after brazing. The melting range of boric acid is lower than that of the borates, but higher than that of the fluorides.

Wetting agents are used in paste and liquid fluxes to promote the flow and spread of the flux on the work metal. The agents that are used must not interfere with the normal functions of the flux.

Water is present in brazing fluxes either as water of hydration in the various chemicals, or as an addition to make the flux into a paste or a liquid. Water of hydration is removed by calcining the chemical that contains it. Water that is used to dilute fluxes must be tested for mineral content. Excessively hard water should be avoided. Sometimes alcohol is substituted for water, or demineralized water is used.

Flux Types. For torch brazing of low-carbon and low-alloy steels, fluxes can be grouped roughly into three general types, as shown in Table 2. The flux constituents are formulated so that their useful temperature range meets the applicable filler-metal temperature requirements. Boron compounds are present in all three types because of their stability. To be compatible with the silver alloy filler metals, fluorine compounds are added to lower the useful temperature range and the viscosity of the flux, as indicated by type 3A. Boron compounds alone are used in type 5 flux because the higher useful temperature range and viscosity are compatible with the copper-zinc filler metals. Type 3B flux falls between type 3A and type 5 in useful temperature range, and represents a second choice for either filler metal, in the torch brazing of steel.

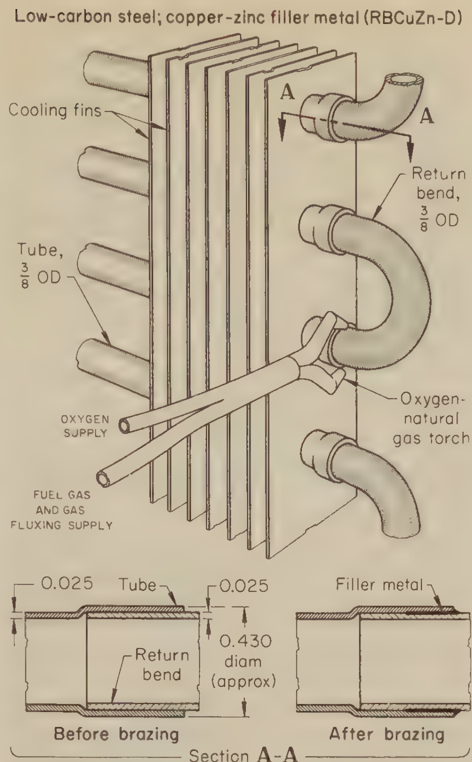


Fig. 12. Portion of an oil cooler showing the method used for brazing return-bend joints. Copper-zinc alloy filler metal with gas fluxing proved less costly than silver alloy filler metal with liquid flux. (Example 583)

Gas Fluxing. In some applications of manual and automatic torch brazing, more efficient production can be realized by applying flux directly through the gas flame. This is accomplished by bubbling the fuel gas through a small tank containing the flux in the form of a volatile liquid. A typical gas-fluxing assembly is shown in Fig. 11. Vaporized flux is entrained with the fuel gas, which flows to a conventional torch or burner, mixes with oxygen (or air) and burns in the flame, depositing a thin, uniform film on the workpiece. In liquid form, the flux is a type of methyl borate produced from methanol, boric acid and diluents, under moisture-free conditions. Its temperature range corresponds to flux type 3B (Table 2).

Any fuel gas that is free of water vapor can be used with gas fluxing. In the presence of water vapor, the fluxing agent (boric acid) is precipitated in the form of a whitish, crystalline solid. This condition is prevented by installing a chemical drier (calcium chloride) in the line and by substituting ethylene glycol for the water used in flashback arresters. For best results, a neutral flame is used. Brazing is done using goggles with number 4, 5 or 6 green lenses, because the flux produces a brilliant green flame that masks the inner flame cone from view by the naked eye.

The flux can be deposited only on areas that the flame can reach. Gas fluxing has two principal uses:

1. In manual torch brazing and especially in braze welding of low-carbon steel, where rods of copper-zinc filler metal are used in joints having varying or relatively large clearances, the flux is used for brazing the joint and for protecting the base metal from oxidation. In such applications, gas fluxing eliminates the need for continually dipping the filler-metal rod in flux or for making use of the more costly flux-covered rods. For postbraze cleaning, the flux can be removed by washing in hot water (150 F). Cost savings are most significant in production braze welding operations.
2. In applications where joint clearances are closely held, and also in applications using silver alloy filler metals, a suitable flux (type 3A or 3B, Table 2) must be applied to the joint before heating. Under these conditions, gas fluxing is used mainly to protect the part from oxidation when surface appearance is important or when parts are to be subsequently plated. As an aid in fluxing, it also reduces the amount of paste flux that otherwise would be required and, in hand-fed operations, reduces the amount of silver alloy filler metal used.

Gas fluxing is also used in a variety of semiautomatic and automatic torch brazing equipment. In addition to its use in joining low-carbon steel, it is employed in brazing alloy steels, stainless steel, copper and copper alloys, and nickel alloys, and in joining these metals to each other.

Applications of gas fluxing in the torch brazing and braze welding of steel include automotive and machinery parts, bicycle and motorcycle frames, metal furniture, doors and partitions, and many kinds of special fixtures.

In one plant, a window bracket was made from a flat piece of cold rolled steel and a 2-in. length of tubing of the same kind of steel. At first, the assembly was torch brazed using a paste or powder flux with an RBCuZn-D rod. When the brackets were chromium plated after brazing, a rough, peeling area appeared next to the brazed joint.

A change was made to gas fluxing, using the same filler metal. Fillets were smooth and sound, and could be chromium plated satisfactorily. The cleanness of the joint made with gas fluxing was responsible for the better adhesion of the electroplate.

In another plant, the flow of subassemblies required for final assembly was processed through separate stations, each manned by a torch brazing operator. Highly skilled operators combined brazing and braze welding techniques for economy of time and motion, as described in Example 526, in the article on Oxyacetylene Braze Welding.

Changing from a silver alloy filler metal with a brushed-on flux to a copper alloy filler metal and gas fluxing may prove advantageous, as in the example that follows.

Example 583. Copper-Zinc Brazing With Gas Fluxing vs Silver Alloy Brazing With Paste Flux (Fig. 12)

Return bends on low-carbon steel oil-cooler tubes like those shown in Fig. 12 were formerly torch brazed using BAg-2 silver alloy filler metal and type 3A flux. The paste flux was brushed on after the tubes were assembled. The brazed assemblies had to be carefully flushed and dried, both inside and out, to remove corrosive flux residue. The joint was heated with a dual-tip torch fed by oxygen and natural gas to produce a flame temperature of about 3300 F. Filler metal was hand fed to the joint.

A change was made to RBCuZn-D filler metal and, at the same time, gas fluxing replaced the use of paste flux. The joints continued to be sound. The cost of the replacement filler metal was considerably lower than that of BAg-2, and the need for washing to remove flux residue was eliminated. In both methods, the actual heating time was about 3 sec.

Destructive tests showed that the joint appeared more like a braze weld. The flow of the copper-zinc filler metal through the joint was less complete than that of the silver alloy. However, hydrostatic and air leak tests on all production parts showed satisfactory joint quality.

Advantages of Torch Brazing

The advantages of torch brazing for several types of applications have been pointed out in examples in this article. In Examples 574, 575, 576 and 577, fixturing of the assembly was either not needed or simpler when torch brazing was used. The appearance of the joint was also a factor in the selection of torch brazing over welding in Example 576. Feasibility and cost determined the choice in Examples 578 and 580. In Examples 578, 584 and 585, production quantity was too low to warrant investment in equipment for other brazing processes. In Example 586, torch brazing was selected because it localized the heating. Induction brazing with a single wraparound inductor would have heated a wider band, which might have resulted in damage to the part.

Example 584. Torch Brazing Experimental Assemblies (Fig. 13)

Only three experimental cylinder-cap assemblies of the size shown in Fig. 13 were needed. The most suitable method for joining the low-carbon steel components would have been either induction brazing with silver alloy or furnace brazing with copper. But the equipment was not available and the small number of parts needed did not warrant its procurement. The three assemblies were therefore torch brazed.

The filler metal used was silver alloy BAg-1a, and the flux was type 3A. The assemblies were positioned cap-end down, and the filler metal was hand fed to the joint. Diametral clearance between cylinder and caps ranged between 0.000 and 0.006 in.

Example 585. Use of Torch Brazing To Attach a Reference Clip to a Vane Assembly (Fig. 14)

The air-vane assembly shown in Fig. 14 had to be carefully positioned during a subsequent operation, and therefore a calibrating surface was needed. This was supplied by brazing a small protractor clip to the end of the vane. Because of the thinness of the skin and the criticality of the angle of the protractor clip, care had to be taken not to overheat the joint area.

The surfaces of the low-carbon steel components were first cleaned with a solvent to remove oil and grease, and then further cleaned with an abrasive wheel to remove oxides and scale. Type 3A flux was applied to the cleaned surfaces.

The protractor clip was positioned carefully and bolted to hold it in position. The clip and surrounding surface were heated by the torch to drive off moisture and to activate the flux. As the flux became active, silver alloy filler metal, BAg-1, in wire form was hand fed to the joint. The torch was removed as soon as the filler metal flowed into the joint. When the assembly cooled, residual flux was removed by washing, the joint was scrubbed with a wire brush, and the assembly was dried and rustproofed.

The reason for torch brazing rather than using another brazing method was that only ten assemblies were to be made. In addition, torch brazing made it possible to observe the operation as heat and filler metal were applied.

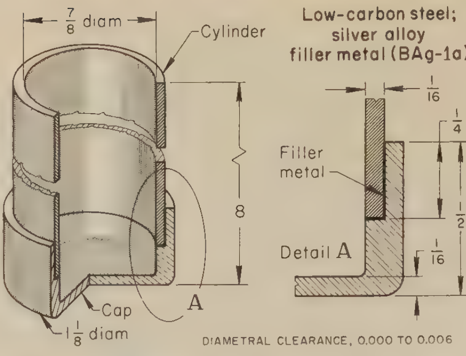

Fig. 13. Cylinder-cap assembly that was torch brazed because quantity to be brazed was low (Example 584)

Example 586. Use of Torch Brazing To Localize Heating (Fig. 15)

The low-carbon steel assembly shown in Fig. 15 was part of an electrical connector. Three small plugs like the one shown in detail A were distributed around the inner wall. They were to be used for locating purposes. The positions of the plugs were staggered around the circumference of the connector barrel and were approximately $\frac{1}{4}$ in. from a hermetic seal, which had been brazed in place in a previous operation.

The plugs had to be brazed into place without impairing the hermetic seal. There were two possibilities: induction brazing, in which a zone all the way around the barrel would be heated and the three plugs would be brazed simultaneously; and torch brazing, in which each of the plugs would be brazed individually.

The possibility that the induction-heated zone might spread wide enough to affect the hermetic seal led to the choice of torch brazing, even though it was more time consuming. A small spot inductor could have been used to braze the plugs one at a time, but the probable saving in brazing time did not warrant the investment in equipment.

The plugs had $\frac{1}{32}$-in.-diam shanks that were press fitted into holes in the connector barrel. Length of the shanks was less than the thickness of the barrel wall, so a small well was left at the outside end of each plug to retain flux and filler metal; each was brazed and cooled individually.

The filler metal used in brazing both the seal and the plugs was BAg-3; flux was 3A.

Removal of Flux After Torch Brazing

There are five major reasons for removing residual flux after brazing: (*a*) the joint cannot be inspected for soundness until the cover of flux residue is removed; (*b*) the joint may be bound together by the flux in the semblance of a brazed joint, only to break apart later in service; (*c*) in fluid or pressure service, the flux may block pinholes that might withstand a pressure test, but would leak soon after being placed in service; (*d*) if left on the joint, the flux attracts available water, resulting in oxidation and corrosion; and (*e*) painting, coating or plating cannot be done satisfactorily on areas covered with flux residue.

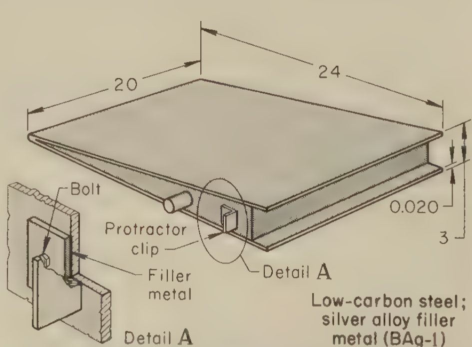

Fig. 14. Air-vane assembly on which protractor clip was brazed for alignment in subsequent assembly (Example 585)

If parts have been well cleaned before brazing and not overheated during brazing, flux residue can usually be removed by a hot water rinse followed by thorough drying. To avoid corrosion, flux removal should be delayed no more than 48 hr.

A quick method of removing glasslike residues is to quench the joint in cold water after brazing and thus to crack off the deposit by thermal shock. However, in some applications, such treatment may cause distortion of the brazed assembly.

Scrubbing, applying a steam jet, and most of the standard abrasive techniques, such as wire brushing and abrasive blasting, are also used to dislodge stubborn flux residues, provided the operation does not impair the function of the assembly.

When flux cannot be removed from steel assemblies by rinsing in cold or hot water, a cold 5% solution of sulfuric acid will prove more effective. The solution may be warmed to accelerate the action, provided care is taken to prevent excessive attack on the assembly. A small addition of sodium dichromate to the solution makes the action even faster, but the time of immersion must be carefully controlled to avoid the greater risk of etching the steel.

Phosphate solutions similar to those used for cleaning steel are effective flux removers and have the added advantage of giving carbon steel assemblies a temporary protective coating. However, the coating will hamper subsequent brazing operations.

Boric acid, as applied in gas fluxing, can be removed by washing in clean water heated to at least 150 F. (Boric acid is only slightly soluble in cold water.)

Mixed borax and boric acid fluxes are more difficult to remove than other types. Fortunately, moisture absorption and corrosion are minimal with borax fluxes. In fact, rather than risk damage to delicate assemblies, such as electronic components, when mixed borax and boric acid fluxes are used the flux is sometimes allowed to remain after brazing. The manufacturer accepts the possibility of some corrosion occurring and some imperfect joints being hidden under the flux.

These fluxes can be removed by quenching, shot blasting, sand blasting, chipping, filing, scraping and wire brushing. The rate of solution in water is slow, and even if a dilute sulfuric acid solution is used, the necessary period of immersion may be inconveniently long for production work.

Fluoride fluxes are soluble in water and are much easier to remove than borax fluxes. Holding under running

cold water while brushing with a wire or bristle brush will usually suffice. Alternatively, the assemblies may be boiled in water for a few minutes, and then rinsed in cold water. Dilute sulfuric acid solutions and phosphate solutions can also be used for quicker results. The residue of fluoride fluxes is hygroscopic, and if the assembly is not quenched after brazing, it is often advantageous to postpone the postbrazing cleaning for 24 hr. Under normal atmospheric conditions, the residue will absorb moisture during this period and will become more readily soluble in any of the solvents previously mentioned. Flux removal should never be delayed for more than 24 hr. In 48 hr, many types of steel will begin to corrode.

If a fluoride flux is difficult to remove, the cause can usually be traced to the brazing operation. If too little flux is used, the residue is a hard, cokelike oxide. If the flux is heated above its rated operating temperature, or for too long a time, it is likely to leave a hard, glasslike residue similar to that left by borax fluxes.

Care should be taken to prevent fluoride residues from entering the body via mouth or skin openings. Gloves should be worn, and the hands washed well before handling food.

Preparation for Plating. If the assembly is to be electroplated, a suitable treatment is immersion in a solution of 5% sulfuric acid and 3% sodium or potassium dichromate followed by a water rinse and a hydrochloric acid pickle. The anodic treatment that is normally used for cleaning before plating will remove the last traces of flux, but should not be used for removal of all flux because the electrolyte will quickly become contaminated with flux.

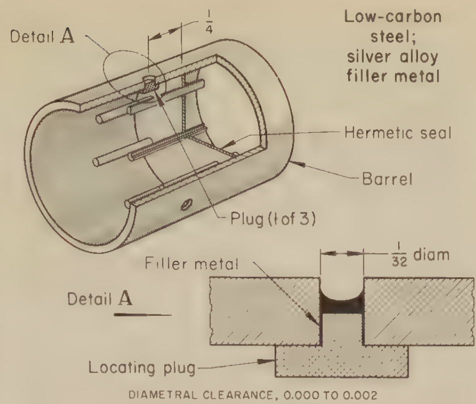

Fig. 15. Connector assembly with locating plugs that were torch brazed in position one at a time to avoid heat damage to a hermetic seal (Example 586)

Safety

The use of safe practices to avoid accidents, and the rules for applying these practices, are discussed in the section on Safety on page 578.

Failure to follow simple rules is a major cause of accidents in brazing and welding operations. Gases must be shut off at the regulators; gas savers should never be used to shut off supply for more than a short time. Even a small leak in the hose line can lead to a potentially dangerous accumulation of gases after working hours, when exhaust fans are not in operation.

Other Examples of Torch Brazing

Other articles in this volume contain examples involving torch brazing, either as the original method of joining that was superseded by a more satisfactory method, or as the preferred method for joining a particular type of alloy or a particular structure.

The following table lists nine such examples, with brief descriptions of the members joined. In each case, a silver-base alloy was used as the filler metal. Manual torch brazing was used in all cases except for Example 568, where the operation was automatic.

Other Examples of Torch Brazing in This Volume

Example 565: Lever assembly of low-carbon steel sheet and tubing
Example 566: Can-opener blade assembly of low-carbon steel sheet, tube and bar
Example 567: Plate-and-bushing assembly of low-carbon steel
Example 568: Shaft pin of free-machining steel to low-carbon steel lever arm
Example 592: Joining the corner seams of a formed low-carbon steel letter tray
Example 615: Tubes of type 304L stainless steel to type 304L sleeve for high-vacuum service (cadmium-free filler metal)
Example 627: Pure nickel tube to type 304 stainless steel tube
Example 629: Ten joints in a stainless steel temperature sensor; type 302 to type 303, and types 302 and 304 to 304
Example 630: Copper alloy 230 (red brass, 85%) wave-guide tube to flange of type 304 stainless steel

Induction Brazing of Steel

*By the ASM Committee on Brazing of Steel**

INDUCTION BRAZING is a process in which the surfaces of components to be joined are selectively heated to brazing temperature by electrical energy supplied from an induction heating unit. The energy is transmitted to the workpiece by induction, rather than by electrical connection, using an inductor or work coil. Heating is the result of eddy currents or I^2R losses in the work metal which, by virtue of its electrical resistivity and the flow of induced alternating current through it, generates heat. When the work metal being heated is ferromagnetic, as are most steels, some slight additional heating results from hysteresis. However, all heating due to hysteresis ceases when the temperature of the work metal is raised to the Curie point (about 1420 F). Above this temperature, heating by electrical resistance continues at a reduced rate as the temperature rises.

Most of the heat induced in the workpiece by electric current is limited to a thin surface layer close to the inductor. Distribution of heat to other areas of the workpiece depends on conduction. In general, heat flow by conduction, although fairly rapid, is minimized by the rapidity at which induction heating takes place. The depth of heating by induction depends mainly on the frequency of the alternating current.

As the frequency is increased, both the theoretical depth of current penetration and the depth of the heated zone in the workpiece decrease. For example, the theoretical depth of current penetration is about 0.035 in. at a frequency of 3 kHz but decreases to about 0.003 in. at 500 kHz†.

Frequency Range. Frequencies used for induction brazing can range from the powerline frequency of 60 Hz to approximately 450 kHz. The higher frequencies should be selected when shallow heat penetration is desired. In the induction heating of steel for surface hardening, shallow heat penetration at high power inputs is generally desirable for rapid heating and control of depth of heating. In the brazing of steel components, however, deeper and more uniform heating of the two parallel surfaces that will form the joint may be preferable, and the advantages of a high operating frequency, such as 450 kHz, may be more suitable for the brazing of nonferrous metals or the brazing of steel to a nonferrous metal or a nonmagnetic (austenitic) steel. The role of frequency in induction brazing is considered in detail in the section on Selection of Frequency in this article. For the majority of brazing applications, the frequencies used are seldom below 10 kHz, the peak frequency obtainable from motor-generator power-supply units.

Process Capabilities

The primary advantage that induction brazing has over other brazing processes is high-speed localized heating, which minimizes oxidation and thus reduces cleaning requirements. Because the heating is localized, warpage is often less than when the entire assembly is heated, and the nature and extent of metallurgical changes, such as the softening of cold worked or heat treated metal, are also minimized.

*For committee list, see p 593. Some examples in this article were contributed by other Metals Handbook welding and brazing committees.

†Hz = Hertz, or cycles per second; kHz = kiloHertz, or kilocycles per second.

Most of the variables in induction brazing are machine controlled. Therefore, operators require a minimum of training and skill. Induction brazing is capable of making clean, neat joints without excessive spatter or excessive flow of filler metal to areas where it is neither needed nor wanted. This latter capability accounts, in part, for the extensive use of the process in the electronics and electrical industries. For instance, in induction brazing of the electrical-coupling assembly shown in Fig. 1, nickel-plated ceramic pins, by which electrical connections were made, were not bridged when brazed into the diaphragm seal of the coupling body. (Bridging, in this application, refers to the flow of filler metal from one pin to another, thereby establishing a silver connection between pins.) The coupling body was machined from ⅝-in.-diam free-machining 1010 steel bar stock. The pins were plated with nickel, to make a brazeable surface. Holes through the diaphragm were chamfered to obtain a good fillet of filler metal without excessive overflow. A small amount of AWS type 3A flux was applied, and the filler metal (BAg-1) was carefully measured and preplaced to avoid excessive flow and bridging of the ceramic pins. Heat was closely controlled by timing each cycle.

Metals Brazed. With the exception of aluminum and magnesium, most of the common metals and alloys that can be joined by other brazing processes can be brazed satisfactorily by induction. Other exceptions, based largely on feasibility and cost, usually involve brazing at extremely high temperatures in vacuum or a protective atmosphere. Although it is possible to induction braze in vacuum or in some protective atmospheres, such procedures are costly and are limited to specialized applications. Most induction brazing is done without the protection of a prepared atmosphere. Therefore, the heating and cooling must be rapid and the temperature attained must be relatively low (seldom higher than 1550 F), or the workpieces will oxidize excessively beyond the flux-protected joint.

Dissimilar metals can be induction brazed, although special techniques must be employed to equalize differences in heating rates when a magnetic metal is induction brazed to a nonmagnetic metal, or to equalize differences in coefficients of thermal expansion of dissimilar metals being induction brazed (see discussion and Example 590 in the section "Brazing of Dissimilar Metals", on page 639).

Size Limitations. Induction brazing is most conveniently applied to small and medium-size assemblies. Brazing large assemblies, such as cylindrical bodies several feet in diameter, would entail major problems in coil construction, coupling and circuit balancing, even with an adequate power supply.

Brazing temperature also may impose a limit on the size of assembly that can be brazed by induction. Power requirements increase with an increase in the area to be heated and the required brazing temperature.

Nevertheless, the practical limit on the maximum size of an assembly for induction brazing normally exceeds that for furnace brazing. In furnace brazing, the entire assembly must be heated to the brazing temperature, whereas in induction brazing, the inductor is designed to restrict heating to the joint area.

Shape Limitations. Assemblies of almost any shape can be heated for brazing by induction, depending primarily on limitations imposed by construction of a suitable inductor, matching the impedance of the inductor and setup with the output characteristics of the power supply, efficiency in heating, and cost. Although many inductors of intricate and unusual design have been constructed, practical limits are entailed in the bending and forming of copper tubing of a given diameter and wall thickness, as well as in providing the inductor with enough cooling water to prevent overheating, and in matching impedances.

Some of the problems associated with large assemblies have been overcome by rotating, or otherwise moving, the workpiece in relation to the inductor to develop an intricate heating pattern with a relatively simple inductor. In this manner, for example, a cylindrical object can be heated evenly while it is rotating within a simple, nonconforming "hairpin" inductor.

Maximum efficiency in heating is generally obtained when heating the external surface of a cylinder, using a simple ring inductor of one or more turns that surrounds the external surface. Such an inductor is also among the easiest to construct and to cool. In contrast, heating the internal surface of a hollow cylinder by locating the inductor inside the cylinder is considerably less efficient and requires a much larger power input to heat the same volume of metal in a given time. Nevertheless, such coils are often used when adequate power is available.

At the higher operating frequencies, such as those provided by vacuum-tube power supplies, workpieces that have sharp corners or projections such as threads are susceptible to damage in induction brazing, because the crests or points will overheat, and may even melt, before the joint reaches brazing temperature. There are techniques, however, that limit damage to thread profiles (see Example 595).

Although induction brazing is by no means limited to assemblies that are self-jigging, this design feature, as in furnace brazing, will often eliminate the need for special fixturing. Assemblies that are not self-jigging by virtue of design may often be temporarily held together by staking or tack welding. The use of fixtures in induction brazing is not uncommon, but may impose special requirements regarding the selection of materials from which the fixtures are to be made. For fixtures that are to be located close to (2 in. or closer) any portion of the inductor or connections leading to the inductor, heat-resisting nonmetallic materials, such as cemented-asbestos board, ceramics and quartz are preferred. Aluminum and copper are also useful fixture materials, provided that they are far enough from the inductor not to be heated by it. Fixtures that are allowed to become heated will deteriorate and will detract from the efficiency of the brazing operation.

Matching Impedance. An important limitation in all induction heating operations entails the requirement for matching impedance. All of the characteristics of the inductor (or work coil), including its diameter, number of turns, length, coupling with the work load and operating frequency, together with work-load variables such as the electrical resistivity of the workpiece, combine to constitute a factor known as impedance. Heating the workpiece depends on obtaining sufficient power in the inductor, which, in turn, depends on matching the impedance of the setup (inductor and workpiece) with the output characteristics of the power supply (generator or oscillator).

In essence, the circuit that constitutes the inductor and setup must be in preferred balance or resonance with the circuit of the power supply, or the transfer of energy from the power supply to the inductor and workpiece will not be consumated. Thus, when a multiple-turn inductor is substituted for a single-turn inductor, or any other major variable of the work-load circuit is changed, some readjustment usually must be made in the power supply circuit to compensate for the resulting change in impedance. Depending on the type of power supply employed, matching transformers or variable capacitors are commonly used for this purpose. However, it should be recognized that with any power supply the ability to match impedance is limited; inductor design and work load are thereby affected.

Quantity Limitations. Although induction heating equipment is relatively expensive, and although most induction brazing setups (inductors and fixtures) are designed for one assembly only, the induction brazing process is not limited to mass repetitive production. Because most inductors are simple and inexpensive to construct and many brazing fixtures are neither elaborate nor expensive, the process is also well suited for handling small quantities of assemblies in a variety of shapes and sizes. Also, because the same induction heating machines are often capable of performing a variety of heat treating operations, induction brazing has been widely adopted by both jobbing shops and captive plants that perform both brazing and heat treating. For high-volume production of assemblies of relatively few designs, the compactness of induction brazing equipment enables a plant with limited space to set up for induction brazing.

Automation. When production quantities warrant the investment, the induction brazing setup can be partly or fully automated.

Brazing Combined With Heat Treating. Because the temperatures used in induction brazing are frequently close to those used in heat treating, the two operations can often be performed simultaneously or in sequence (see Examples 589 and 591). In some applications, significant cost savings can be realized by brazing, austenitizing for hardening, quenching (usually with a spray) and tempering in an automated sequence of operations.

Principles of Operation

In induction brazing, the distribution of heat to sections of the joint depends largely on the contour of the inductor and the proximity of the inductor to the surfaces to be heated. The rate of heating varies inversely with the distance between the inductor and the workpiece surface. This relationship is not linear; the heating rate drops very rapidly as the distance is increased. Increasing the distance between the inductor and the joint reduces the thermal gradient across the joint but, at the same time, rapidly reduces heating efficiency. At some distance from the inductor, coupling between the inductor and workpiece is broken, and all heating ceases.

Apart from the inductor and the energy transmitted by it to the workpiece, the heating of a metal by induction for any purpose is also influenced by the mass, electrical resistivity and magnetic permeability of the metal. Under identical conditions, a thin section will heat to a given temperature faster than will a thick section, a metal with high electrical resistivity will heat faster than one with low resistivity, and magnetic metals will heat faster than nonmagnetic metals.

Brazing of Steel. Carbon and low-alloy steels and ferritic and martensitic (400 series) stainless steels are magnetic and have comparatively high electrical resistivity; therefore, they will heat very rapidly with less power input than would be required for heating a nonmagnetic, low-resistivity metal such as copper. Hysteresis losses play a minor role in the heating of magnetic metals; rapid heating is primarily the result of high electrical resistivity and magnetic linkages.

When brazing steel to steel, differences in the mass of the components are often significant. Much more energy must be introduced into the heavier component than into the lighter component to achieve a similar temperature rise in each. If the mass of one component is very much greater than that of the other, it may be advisable to generate all of the heat energy in the heavy component and to allow the light component to heat solely or largely by thermal conduction.

Brazing of Steel to Copper. In brazing steel to copper, the steel will heat much more rapidly than the copper unless provision is made to equalize the heating rates. In practice, this is accomplished by coupling the inductor more closely to the copper than to the steel or by adding more turns to that portion of the inductor heating the copper. Similar provision must be made in brazing steel to brass or to austenitic (nonmagnetic) stainless steel. Steel will heat much faster than either of these metals, although the differential in heating rates is less than that for steel and copper.

Power Supply

Induction brazing is usually done at frequencies of 10 kHz and higher. A variety of types of commercial power supplies are available, ranging in rating from about ½ kilowatt to several hundred kilowatts, thus providing a wide selection that can be used for single or multiple inductors.

1010 steel brazed to nickel; silver alloy filler metal (BAg-1)

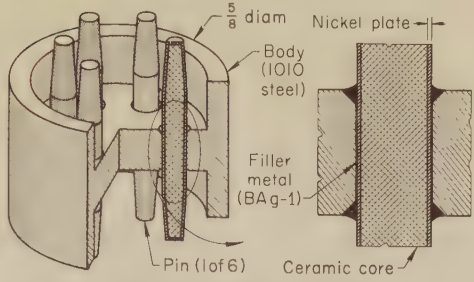

Fig. 1. Electrical coupling in which nickel-plated ceramic pins were induction brazed to a steel body

Motor-generator units are available with power-output ratings from 5 to 500 kw or more and operating frequencies of 960 Hz to about 10 kHz. A typical motor-generator unit consists of a high-frequency generator driven by a motor, capacitors connected across the output terminals to offer a high power factor, a transformer between inductor and generator with a turn ratio to match a desired work-load impedance, and electrical controls such as voltage regulators, switches, meters, and automatic timers.

Most motor-generators are used with a 60-Hz power input and are designed to deliver full power at a particular voltage, current, and power factor. In order to transfer power from the generator to the workpiece, the generating source must be matched to the work load, a function that is performed by the matching transformer and, when required, by altering the turns of the inductor or work coil.

Solid-State Power Supplies. Solid-state, high-frequency power supplies can be substituted for motor-generator units to provide power outputs of 50 kw or more at a maximum operating frequency of 10 kHz. Based on cost, these units are not competitive with the motor-generator at lower power.

The solid-state unit provides high-frequency power through the use of silicon controlled rectifiers, together with automatic power-factor control to compensate for changes that occur at the inductor when the resistivity of the work metal increases with increasing temperature or when a magnetic work metal passes the Curie point. The unit consists of a rectifier section, operating on 60-Hz alternating current and producing a substantially constant level of direct-current voltage, an inverter section producing variable-frequency alternating voltage, a series reactor, an output transformer, and power-factor corrective capacitors.

Vacuum-tube units are available with rated capacities ranging from ½ to 600 kw; output frequencies usually range from 180 to 450 kHz, although even higher frequencies are available. Vacuum-tube units are often referred to as "RF" or radio-frequency units.

Vacuum-tube units consist of a power-supply section and an oscillator section. The power-supply section provides the high voltage for the oscillator tube after rectification to a pulsating direct current, usually by mercury-vapor tubes. The oscillator tube and a tank circuit consisting of a matched inductor and capacitor comprise the oscillator section. The oscillator tube controls the amount of electrical energy delivered to the tank circuit, from which the energy is removed by the coupled load. A small and proportionate amount of the power in the tank circuit is fed back into the grid of the oscillator tube to control the current that is delivered to the tube, and the tube in turn controls the amount of electrical energy entering the tank circuit. The frequency developed in the converter is determined by the inductance of the tank coil and by the capacitor, which form a parallel tuned circuit. A load-matching network electrically coupled to the tank circuit is used to transmit tank-circuit energy to the work.

Selection of Frequency. Power for most induction brazing operations is supplied by high-frequency induction heating equipment, usually with operating frequencies of not less than 10 kHz. However, the range of suitable frequencies higher than 10 kHz is very broad and suggests that, in brazing, the factors of power input and matching impedance outweigh frequency in importance. In this respect, the heating requirements for induction brazing differ markedly from those of induction heating for surface hardening, which requires very high frequencies, or of billet heating, which is most efficient at lower frequencies.

Motor-generator units with frequencies of about 10 kHz and vacuum-tube units with frequencies as high as 460 kHz can be used for induction brazing.

In general, motor-generators are more efficient for heating large and heavy components at high power inputs, using inductors with similar impedance values and close coupling. Vacuum-tube units are generally more versatile, making it possible to process a wider variety of brazing and other heating applications with the same power supply. They often present fewer problems in matching impedances, and permit the use of inductors with close or loose coupling, or combinations of both in the same multiple-turn inductor, which is often advantageous in induction brazing of dissimilar metals. Vacuum-tube units also make it possible to combine brazing and thin-case hardening in a single operation.

For heating steel, the lower frequencies of the motor-generator can more often be tolerated than for heating copper, and may be desired. Because steel is only a fair conductor compared to copper, for the same power input, the surface heats faster and heat penetration is much slower.

Inductors

Among the many variables that affect the pattern of heating obtained by induction and that, therefore, are pertinent to induction brazing, are: (*a*) the shape of the inductor that produces the magnetic field, (*b*) the number of turns in the inductor, (*c*) the spacing between turns of the inductor,

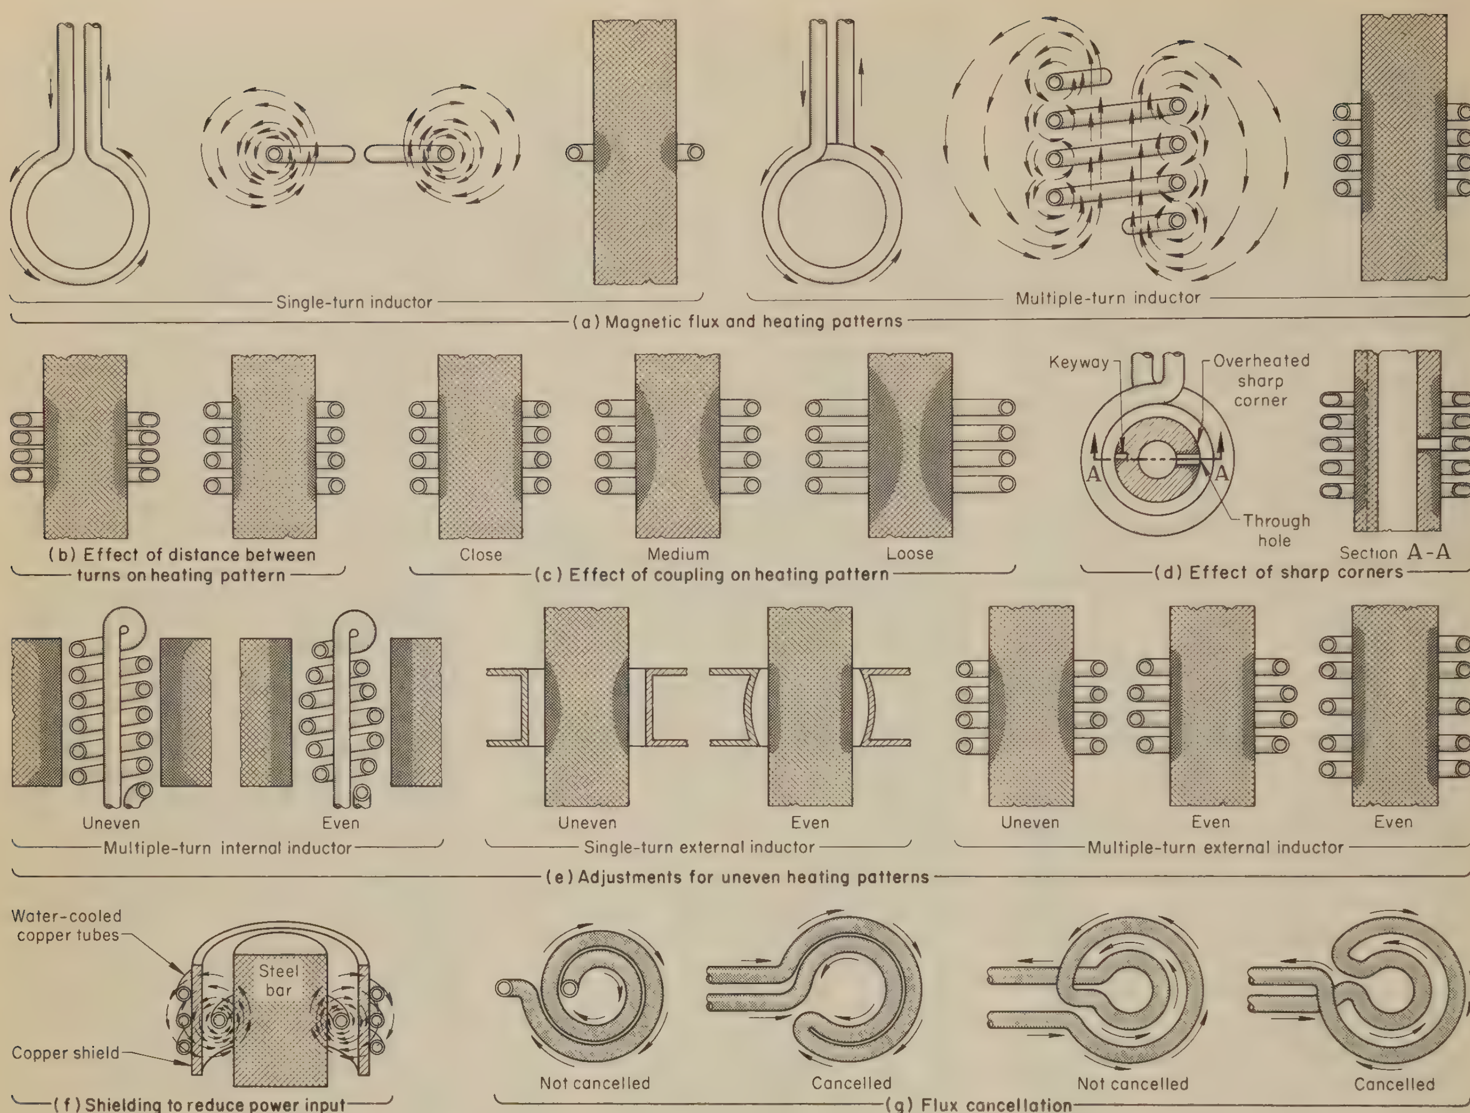

Fig. 2. Magnetic fields and heating patterns produced by various inductors

(*d*) the distance (air gap) between the turns of the inductor and the workpiece, (*e*) the presence of sharp corners on that portion of the workpiece within the magnetic field, (*f*) the presence of metallic shields within or near the inductor, (*g*) the operating frequency, and (*h*) the alternating-current power input.

Magnetic Fields and Heating Patterns. Examples of magnetic fields and heating patterns produced by induction are shown in Fig. 2. The patterns of magnetic flux for a single-turn and a multiple-turn inductor are shown in Fig. 2(a), along with the heating patterns developed by these inductors. The effect of inductor pitch, or the distance between turns in a multiple-turn inductor, on heating pattern is shown in Fig. 2(b); finer-pitch windings develop a deeper heat pattern than loose windings. The effect of coupling, or the air gap between inductor and workpiece, on heating pattern is shown in Fig. 2(c). The effect of sharp corners, such as those on a keyway, on the heating pattern developed in a multiple-turn inductor is shown in Fig. 2(d); the heat builds up excessively at sharp corners. Figure 2(e) shows modifications in heating pattern that result from modification of coil contour in a multiple-turn inductor designed for heating internally; contour of the inductor tube in a single-turn inductor; and coupling, coil contour and pitch in a multiple-turn inductor.

The use of an external copper shield to dissipate some of the power input of the inductor, and thereby to reduce heating rate and intensity, is illustrated in Fig. 2(f). This same principle was employed in Example 588 to achieve a similar purpose. Although use of a dissipator shield is rare, it is sometimes more effective than a change in coupling in the control of heat input. Finally, the development and cancellation of flux fields is shown schematically in Fig. 2(g). When the turns of an inductor are made to carry the current in the same direction, a flux field is developed, whereas when the turns are made to carry current in opposing directions, magnetic flux is cancelled. Generally, cancellation of the flux field should be carefully avoided; however, as demonstrated in Example 595, cancellation can sometimes serve a useful purpose.

Although, as shown in Fig. 2, heating patterns can be altered in many ways, the rate of heating obtained by induction will depend on the resistance of the work metal to the flow of current induced in it by the inductor. The flow of current will depend on the strength of the magnetic field to which the work metal is exposed.

Inductor Design for Brazing

The success of an induction brazing application depends greatly on the design of the inductor, which, in turn, must be related to the dimensions and configuration of the assembly to be brazed, the heat pattern desired, the heating time that will produce a minimum of work-metal discoloration and oxidation, and the amount of power available. The size of the production run also influences inductor design. A single multiple-turn inductor may suffice for brazing small to medium quantities of assemblies intermittently. A series-type inductor, consisting of two or more single-turn or multiple-turn inductors of identical design, will braze larger quantities of the same assembly intermittently, the increase in production rate usually depending on the number of individual inductors in the series. Finally, assemblies can be induction brazed continuously as they

are carried on a conveyor belt or turntable to hairpin or pancake-type inductors that permit entrance to, and exit from, the heating zone without obstruction.

For the most rapid heating rates, inductors are designed to provide the maximum flow of current in the inductor, and the closest permissible coupling between inductor and workpiece, after consideration of heat distribution, work-handling features, and high-voltage arcing between the turns of the inductor or between the inductor and the workpiece. In practice, considerable variation exists in the design of inductors for vacuum-tube and motor-generator sources of high-frequency power. For the range of frequencies suitable for induction brazing, however, the inductors are made of copper, because of its high electrical conductivity and wide availability at relatively low cost.

Basic Designs. A variety of basic designs of inductors for use primarily with vacuum-tube power supplies with or without matching transformers are shown in Fig. 3. Shown in Fig. 3(a) is a modified single-turn inductor capable of brazing two different joints simultaneously on a single assembly. Figures 3(b) through 3(e) show multiple-turn inductors that have been formed to different geometric shapes to accommodate the contours of specific assemblies. Two types of multiple-turn inductors that are widely used to braze tungsten carbide cutting tips to steel shanks are shown in Fig. 3(f) and 3(g). Unlike the preceding inductors, all of which were made from copper tubing, the inductor shown in Fig. 3(h) is machined from a solid copper bar into which holes have been drilled for water cooling. Two-station and four-station versions of the solid copper inductor are shown in Fig. 3(j) and 3(k).

The so-called "pancake" type of inductor represents a different design category. Double-pancake inductors, such as those shown in Fig. 3(m) and 3(n), are sometimes substituted for the multiple-turn inductors in Fig. 3(f) and 3(g) to braze carbide tips to steel tools. Assuming that both types of work coils are equally satisfactory for brazing, the selection of a pancake-type coil may be based on matching impedance. Because flat pancake inductors permit unobstructed passage of workpieces either above or below them, they are widely used for continuous brazing on conveyor belts (Fig. 3p) and turntables (Fig. 3q); a variety of asbestos products are suitable for conveyor belting and table-top coverings.

Another type of work coil used in induction brazing, especially in conveyor-type operations, is the "hairpin" inductor. Examples of hairpin inductors suitable for use with conveyor belts

Table 1. Compositions, Solidus and Liquidus Temperatures, and Brazing Temperature Ranges for Filler Metals Commonly Used in Induction Brazing

AWS classification	Composition, %: Ag	Cu	Zn	Cd	Ni	Temperature, F: Solidus	Liquidus	Brazing
BAg-1	44 to 46	14 to 16	14 to 18	23 to 25	...	1125	1145	1145 to 1400
BAg-2	34 to 36	25 to 27	19 to 23	17 to 19	...	1125	1295	1295 to 1550
BAg-3	49 to 51	14.5 to 16.5	13.5 to 17.5	15 to 17	2.5 to 3.5	1170	1270	1270 to 1500

or turntables are shown in Fig. 3(r) and 3(s). Because the heating of steel in a hairpin inductor is often restricted to a very limited area, it is usually necessary to rotate the workpiece in order to expose all of the joint area that requires heating to the flux path of the inductor. Rotation is often achieved by forced frictional contact of the workpiece with a stationary guide as it is being conveyed forward in a horizontal plane.

The inductor shown in Fig. 3(t) is typical of a class of rather elaborately contoured work coils that require considerable ingenuity to design and fabricate. This inductor is essentially a double pancake, with each pancake formed to a U-shape contour. The coil surrounds a sufficient area of the joints to ensure uniform heating by induction and conduction. If more time is required to allow for conduction of heat to certain remote areas of the joints, a pulse heating technique (power on, power off, power on) can be employed to ensure uniform heating.

Although inductors designed for heating internally are relatively inefficient in terms of power input to the work load, they are useful in brazing dissimilar metals and in special applications where the use of an external inductor is not feasible. A typical work coil for heating internally is shown in Fig. 3(u). The application requires brazing a portion of the external surface of a hollow copper tube to the internal surface of an externally threaded steel bushing. Heating the assembly with an external inductor would severely overheat the threads unless coupling was loose. With loose coupling, heating would be slow and the copper would heat last, thus jeopardizing the soundness of the brazed joint. In contrast, heating internally favors heating of the copper, so that both copper and steel can be brought to brazing temperature at about the same time. A two-coil internal inductor for brazing two bushings in a hinge simultaneously is shown in Fig. 3(v).

A setup for series-connected, multiple-station inductors linked to a common vacuum-tube power supply and matching transformer is shown in Fig. 3(w). Such a setup is well suited for manual brazing operations involving two or more operators. The inductors can be energized continuously to serve as a common power source for use by the operators, as required. Inductors can be readily disconnected and replaced to accommodate a variety of different assemblies.

Tubing for Inductors. Most inductors are made of commercial copper tubing. The size of the tubing selected for a specific inductor must be large enough to accommodate the current input and to permit an adequate flow of water for cooling. With machines of low power, the tubing may be only $\frac{1}{8}$ in. in diameter, but for units of 20 to 50 kw, it is usually $\frac{3}{16}$ or $\frac{1}{4}$ in. in diameter. (There is available, however, $\frac{1}{8}$-in.-OD tubing with a wall thickness of only 0.018 in. that may be used in the 25 to 50-kw range provided that the flow of pressurized cooling water is adequate.)

Inductors for frequencies obtained from motor-generator units (up to 10 kHz) are generally of two basic designs: (*a*) a single-turn coil, for high current densities (20 to 50 times the generator output current), which is employed to confine heating to a comparatively narrow band or segment; and (*b*) a multiple-turn coil for low current densities (1 to 5 times the generator output current), which is employed to heat a wider or larger area. A step-down transformer is ordinarily utilized between single-turn inductors and the generator; multiple-turn inductors are connected to the generator either directly, or indirectly through a step-down transformer.

The wall thickness of the copper conductor used with motor-generator units is important. For efficient operation at various frequencies, the following minimum wall thicknesses may be used as a guide in constructing multiple-turn coils:

Frequency, kHz	Minimum wall thickness, in.
1	0.120
3	0.070
10	0.040

In the construction of single-turn coils, with which current density may be considerably higher, the values of minimum wall thicknesses listed above should, whenever possible, be multiplied by a factor of three or four.

Cooling. Single-turn and multiple-turn inductors may be formed from tubing or a combination of tubing and solid bus bar. Because of the high current density and the extremely thin cross section in which the current confines itself, water cooling is required. This is accomplished by circulating water through the tubes or through channels provided in the bus bar for that purpose. These channels may be made by drilling connecting holes or milling out a path to make a complete loop around the bore of the inductor, and then plugging the exposed ends of the holes or brazing a copper sheet over the milled passage to make a continuous watertight cooling channel. Cooling passages with cross-sectional areas of 0.050 to 0.125 sq in. will provide adequate cooling at water pressures of 40 to 50 psi for power inputs of 30 to 150 kw.

Water used for cooling should have a hardness of less than 12 grains per gallon. If the water-cooling passages are small in relation to the current load carried by the inductor, it may be necessary to use distilled or deionized water to avoid a buildup of deposits that could eventually stop circulation. Preferably, the water should be filtered to remove foreign particles that might clog small passageways, especially when inductors of intricate design are being used. The water should have an inlet temperature above 70 F and below 95 F, and flow should be sufficient to prevent the outlet temperature from rising above 150 F.

Coupling and Spacing. For efficient transfer of energy, the inductor bore may be $\frac{1}{8}$ to $\frac{1}{4}$ in. larger in diameter than the workpiece — resulting in an air gap, or coupling, of $\frac{1}{16}$ to $\frac{1}{8}$ in. between the inductor and the workpiece. As the bore of the inductor is increased, the workpiece is subjected to a weaker portion of the magnetic field, heating time will be increased, and the heating pattern will be deeper, unless the power density is increased correspondingly. Although loose coupling is seldom desirable for induction hardening, it is often employed in brazing to provide more uniform heating and to avoid overheating the surface.

Inductor coil turns are normally spaced $\frac{1}{16}$ to $\frac{3}{32}$ in. apart. Considerable variation in the heat pattern can be obtained by adjustment of either the spacing between turns or the dimension of the air gap for individual turns.

Filler Metals

Requirements of a filler metal for induction brazing are:

1. Melting temperature lower than temperatures at which the metals being brazed are adversely affected
2. Ability to wet the metals being brazed
3. Narrow melting range (difference between solidus and liquidus temperatures)
4. Sufficient fluidity at the brazing temperature to enable it to flow rapidly through the joint by capillary action
5. Composition chemically compatible with the base metal
6. Ability to form joints that have the required mechanical properties.

Most of these requirements also apply, to varying degrees, in many torch and furnace brazing operations, but a narrow melting range is especially important in induction brazing operations. Filler metals with wide melting ranges flow more sluggishly and are more susceptible to liquation than are alloys with narrow melting ranges. Fast flow is particularly desira-

ble in induction brazing, because time cycles for this process are short.

Selection of Alloy. Compositions, solidus and liquidus temperatures, and brazing temperature ranges for the three silver alloys that are most widely used as filler metals in induction brazing of steel are given in Table 1. Of the three alloys, BAg-1 is used much more extensively than the other two alloys, for two main reasons. First, the brazing temperature range of BAg-1 is the lowest of the three. (A low-temperature brazing range is desirable because the workpiece is normally heated in air, and the lower the brazing temperature, the less will be the oxidation of the workpiece.) Second, the melting range of BAg-1 is only 20 F, making it the most free-flowing of the three alloys. BAg-1 is recommended for brazing steel to steel and is also suitable for brazing steel to copper alloys.

BAg-2 melts at a higher temperature than BAg-1 and has a wider melting range, which makes it less suitable for general-purpose use. However, this property makes BAg-2 more suitable than BAg-1 for large-clearance joints.

BAg-3 is often preferred for joining carbide tips or inserts to steel, because it has good wetting action on carbide (see Example 590). Also this filler metal is preferred for joining stainless steel to itself (as in Example 595), or to carbon steel.

Selection of Form. The filler metals listed in Table 1 may be purchased as spools of wire of various diameters and as strips of various thicknesses, which can be made into preformed shapes if desired. Filler metal is also available in powder form.

Joint design, method of assembly, and cost are the main factors that govern the choice among these forms. Preforms are usually preferred because they can be used with minimum waste and lend themselves to preplacement in or around joints of various designs. Preforms of almost any shape can be made from strip with a simple punch and die or from wire by forming. Some typical preforms are shown in Fig. 4.

Rings often serve as preforms. They can be made by winding wire on an arbor and then slitting the springlike coil lengthwise to produce the rings. Some experimentation is often needed to determine the arbor diameter that will produce rings of the correct diameter after springback.

Many standard types and sizes of rings (and washers) also are commercially available. The sizes are commonly specified by their inside diameters, the rings being meant to fit around joints. The butt-end ring shown in Fig. 4 is of a design that allows for expansion during preplacement. The 1$\frac{1}{16}$-turn ring (see Fig. 4) is designed to allow compression during preplacement inside a joint, and it is specified by its outside diameter.

For some joints, preforms made from strip are more suitable than shapes formed from wire. When large numbers of blanked or formed preforms are needed, their cost may be reduced by buying them from a metal producer, who can reprocess the waste punchings, whereas a user must sell the waste as scrap.

Filler metal in powder form is often used, although if it is used on the exterior of the joint some provision must be made to hold it in place. One method is first to brush the joint with paste flux and then to dust the filler-metal powder lightly onto the flux while it is still wet. Another method is to mix the powder with flux and a binder to form a paste, which is then applied by brushing.

Fluxes

Flux is required for induction brazing. The flux used should decompose oxides without corroding the base metal or the filler metal, should be extremely active because of the short brazing times employed, and should be easy to remove after brazing.

Flux of type 3A (see Table 2, page 628, this volume) meets these requirements and is used for an estimated 95% of the induction brazing applications that involve steel. This flux is composed of a mixture of a wetting agent and one or more of the following materials: boric acid, borates, fluorides and fluoborates, and is effective within the temperature range of 1050 to 1600 F. It is available in the form of paste or powder, and can be mixed to a liquid consistency with water, alcohol or monochlorobenzene.

Paste and liquid fluxes are most often applied to the joint by brushing. When more convenient, flux powder can be sprinkled on or in the joint, or liquid flux can be sprayed.

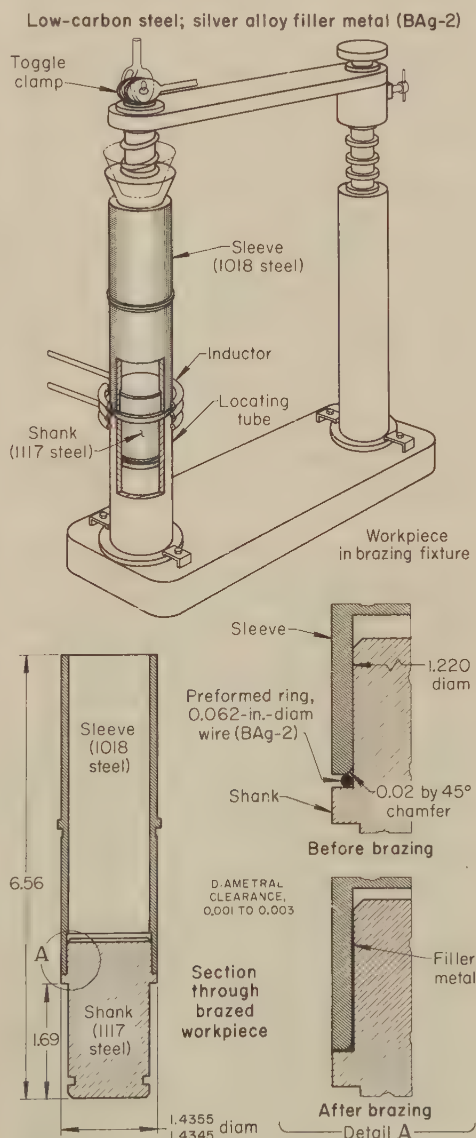

Fig. 5. Induction brazed drive spindle positioned in the inductor by a fixture that finished assembling the components by forcing them together during brazing (Example 587)

Assembly

Methods of preparing joints and assembling the components are generally the same as are used prior to furnace brazing (see the article on Furnace Brazing, which begins on page 593).

The recommended diametral clearance for joints brazed with the filler metals listed in Table 1 is generally 0.002 to 0.005 in. However, based on experience with similar joints, a clearance less or greater than the recommended value is often selected for a specific joint. If the distance the filler metal travels while filling the joint is greater than normal, the clearance (or the brazing temperature, or both) may have to be increased.

Fixturing

Most assemblies that are brazed by induction require some fixturing, even though the components may be held securely together mechanically before being positioned in the inductor. Fixtures can range from a simple locating pin to hold the assembly in the center of the inductor, to an elaborate clamping and holding arrangement. Every assembly must be considered separately in relation to its fixturing requirements. Fixture design is influenced not only by the size and shape of the assembly, but also by the rate at which assemblies are to be produced.

Functions of a fixture may include supporting the assembly, positioning the assembly in the inductor, and holding the assembly securely together during the brazing cycle until the filler metal has solidified.

Sometimes a fixture is designed to perform the additional duty of assembling the components during the brazing cycle, as in the next example.

Example 587. Use of a Fixture That Held an Assembly in the Inductor and Also Forced the Components Together During Brazing (Fig. 5)

An induction brazed drive spindle, consisting of an 1117 steel shank and a 1018 steel sleeve (see perspective in Fig. 5), had originally been completely assembled by hand and supported in the inductor by only a tubular steel locating fixture clamped to a baseplate. For brazing by this method, the joint had a diametral clearance of 0.001 to 0.004 in., the 45° chamfer on the inside diameter of the sleeve was 0.04 in. wide, and the filler metal was a hand-formed ring of 0.062-in.-diam BAg-1 wire. The assembly was brazed at approximately 1350 to 1450 F, using high-frequency (400 kHz) current supplied by a 4-kw vacuum-tube unit.

To increase the production rate and to effect savings in production costs, the fixture was altered to incorporate the spring-

loaded locating cone shown in perspective in Fig. 5. With this arrangement, the assembly was placed in the locating tube with the shank down. The sleeve was centered and held in place by the locating cone, which was forced against the sleeve by the toggle clamp and spring. Before brazing began, the two components of the assembly were held apart by the filler-metal wire (see detail A in Fig. 5). As the assembly was heated and the filler metal melted, the spring-loaded cone pushed the sleeve and shank together, forcing liquid filler metal in two directions to fill the joint.

For brazing with the improved fixture, the maximum diametral clearance of the joint was reduced from 0.004 to 0.003 in., and the chamfer on the sleeve was reduced to 0.02 in. The filler metal was changed to a preformed ring of BAg-2, which has a freezing range 150 F wider than that of BAg-1. Brazing was done at 1300 to 1325 F (the time to reach this temperature range was determined, and the automatic brazing cycle was set accordingly), using the same power supply and frequency as originally. The method was completely successful and the assemblies produced were free from distortion.

The sequence of operations by the improved method was:

1. Clean parts in alcohol.
2. Coat joint with type 3A flux.
3. Place preformed filler-metal ring on shank.
4. Assemble parts in spring-loaded fixture and clamp.
5. Braze at 1300 to 1325 F for 5 to 15 sec, depending on diameter of part (automatic timing); cool in fixture for 5 to 10 sec.
6. Remove assembly, rinse in water at 180 F for 5 min (or place in warm water and hand-brush flux); blow dry.
7. Dip in a rust preventive.

Using the improved method, production time was reduced by 30% and the time needed to straighten assemblies brazed by the original method was eliminated.

Selection of materials for fixtures is especially important. If all components of a fixture are sufficiently remote from the inductor (several inches away) to be unaffected by its magnetic field, materials used for fixtures for other brazing processes are suitable. However, if all or part of a fixture is within about 2 in. from the inductor or the leads to the inductor, the fixture must be made of a nonmetallic, and preferably heat-resisting, material. Several such materials are commercially available; one of the most common is cemented-asbestos board. This material can be machined to various shapes, is electrically nonconductive, nonflammable, and withstands heat. It is supplied in sheets ranging in thickness from ⅛ to 2 in. Other suitable nonmetallic materials include heat-resisting glass, ceramics, quartz and plaster. When use of a metal near the inductor or the leads is unavoidable, aluminum, copper and brass are the preferred metals.

Brazing of Tight Joints

For joints brazed with the high-silver alloys, the recommended diametral clearance (positive allowance) is 0.002 to 0.005 in. However, in some applications this much clearance results in an unacceptable amount of eccentricity in the brazed assembly. A common method of eliminating this in most joints is to use a clearance range of 0.001 to 0.003 in.; with an active, free-flowing filler metal such as BAg-1, acceptable joint penetration can usually be obtained. For some joints, even a diametral clearance of 0.001 to 0.003 in.

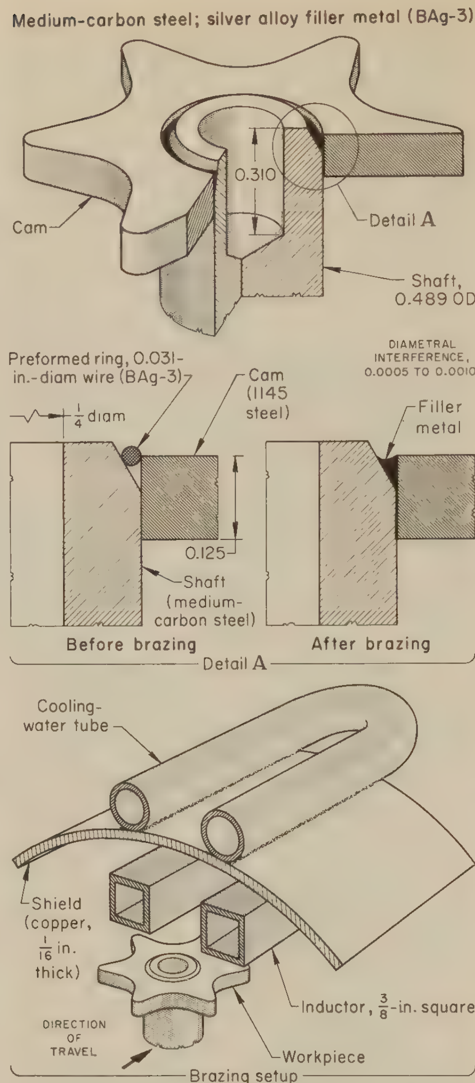

Fig. 6. Induction brazed cam and shaft that had to be assembled with a press fit to maintain concentricity (Example 588)

is unacceptable because of the resulting eccentricity, and a press fit is therefore necessary. Under these conditions, special provisions must be made, as in the example that follows.

Example 588. Induction Brazing With an Interference-Fit Joint (Fig. 6)

Three requirements for the medium-carbon steel cam-and-shaft assembly shown in Fig. 6 demanded special consideration in brazing: (*a*) the specified concentricity necessitated an interference fit of the joint at room temperature, (*b*) the hardness of the bearing area of the shaft had to be retained, and (*c*) the production requirement was 2400 brazed assemblies per hour.

The cam and shaft were assembled with a press fit (slight interference) to ensure concentricity; the end of the shaft was chamfered slightly to facilitate assembly and to form a V-groove for a preformed ring of BAg-3 filler metal (see Fig. 6).

During development of the technique for making the joint, it was found that an excessive amount of heat was being conducted away from the joint area and was resulting in too long a heating time and softening of the bearing area of the shaft. This difficulty was overcome by machining a cup-shape recess in the end of the shaft, as shown in Fig. 6, by employing vacuum-tube power supply units with a frequency of 450 kHz, and by using flat inductors that faced the V-groove.

The production requirement of 2400 assemblies per hour was met by the use of two 25-kw machines, each with two inductors. The assemblies were dipped in liquid type 3A flux and manually placed in holding fixtures mounted on a conveyor traveling at 30 ipm. Preformed 370° rings, 0.480-in. OD and made from 0.031-in.-diam wire, were dropped in place in the grooves.

The assemblies passed under a 36-in.-long inductor that preheated the joint area and dried the flux, and then under a 30-in.-long inductor where brazing was completed. The rate of heating by the inductors was controlled by adjusting the air gap between the inductor and the workpiece. The preheat inductor was inclined to give decreasing air gap; the brazing inductor was horizontal, giving a constant air gap. A water-cooled dissipator shield above the brazing inductor de-intensified the flux field to help reduce the heating rate to the desired level.

After brazing, the heated portion of the assemblies cooled in air to about 800 F during the next 120 in. of conveyor travel and were then sprayed with water during the following 20 in. of travel to remove flux and further cool the assemblies. The assemblies were then ejected automatically from the holding fixtures.

Simultaneous Brazing and Hardening

The use of induction brazing is generally precluded for joining steels if the brazed assembly must be subsequently heat treated at a temperature above the melting temperature of the filler metal, because this would destroy the brazed joints. However, this potential disadvantage of induction brazing can often be overcome by brazing and heat treating in a single operation.

Therefore, in the planning of brazing and heat treating operations, consideration should always be given to the possibility of combining the two operations, or of using the induction equipment for heat treating local areas on the workpiece in a separate induction heating operation (see Example 591).

The example that follows describes a typical application in which brazing and heating prior to quenching were performed simultaneously.

Example 589. Brazing and Surface Hardening in One Operation (Fig. 7)

Originally, the valve-and-tube assembly shown in Fig. 7, which was used in grease-pumping equipment, was furnace brazed with BCu-1 filler metal. The tube was made of 1010 steel and the valve of 1040 steel. The valve face was subsequently hardened by induction heating and water quenching. (Quenching the entire assembly after furnace brazing was unacceptable because it produced distortion.) Furnace brazing, which was subcontracted because the manufacturer did not have suitable equipment, resulted in difficulties. First, the valves did not harden correctly, because they had been decarburized in the brazing furnace atmosphere. In addition, shipping to and from the vendor disrupted plant schedules. The cost of furnace brazing (filler metal, labor, overhead and profit) was $0.1000 per assembly; the cost of induction hardening, $0.1385 per assembly, for a total cost of $0.2385 per assembly. To eliminate these problems, processing was changed to in-plant induction brazing performed simultaneously with heating for quenching, as described below.

Filler metal was 0.040-in.-diam BAg-1 wire formed into 9/16-in.-ID rings. (The use of rings of different size than the part on which they are to be placed, so that they spring into place, is common practice.) A

groove was machined in the valve, as shown in Fig. 7, to make a pocket for the preformed ring. Assembled in this manner, the filler-metal ring just reached the brazing temperature of 1145 to 1250 F when the valve face reached the hardening temperature of 1450 F, because of the characteristic steep gradient caused by the rapid heating. (Had the filler metal reached the hardening temperature, it would have been excessively oxidized.)

A press-fit joint had been employed when BCu-1 filler metal was used with furnace brazing. On changing to BAg-1 filler metal and induction brazing, the diametral clearance between the two components was established at 0.004 to 0.008 in. In practice, clearance was consistently in the middle of this range.

The inductor was made from 3/16-in.-OD copper tubing and had two turns on a 1-in. diameter. The brazing fixture comprised a holder for the tube and a quench ring of low-carbon steel tubing, which surrounded the inductor with a ½-in. clearance to avoid induction heating of the quench ring. The spray of tap water from the quench ring was directed at the face of the valve.

Timing for the brazing cycle was determined visually as follows: An assembly was placed in the machine and the inductor energized. When the operator saw the filler metal emerge and form a slight fillet at the edge of the joint, he noted the time interval, shut off the power, and opened the quench-water valve. After the heating time was established, it was controlled by a timer, but the operator continued to operate the quench-water valve manually.

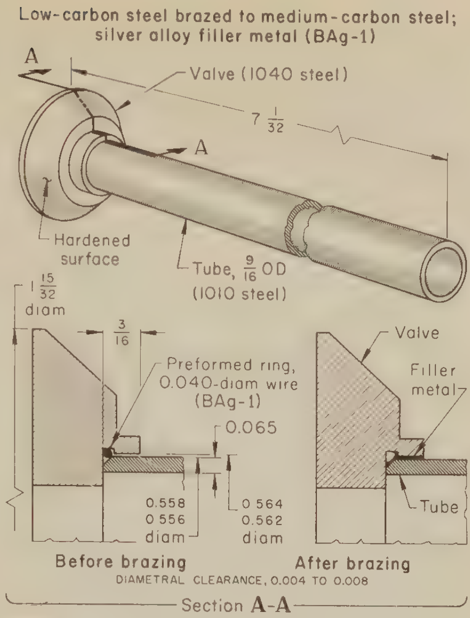
The sequence of operations was:

1 Degrease tube and valve.
2 Place preformed ring of filler-metal wire in groove.
3 Flux mating surfaces of tube and valve with type 3A flux.
4 Assemble components, and place assembly in fixture.
5 Heat for 30 sec.
6 Spray quench.
7 Remove from fixture.

After brazing and hardening, the assemblies were washed and pickled to remove flux. Then they were tempered for 1 hr at 375 F to obtain the required minimum hardness of Rockwell C 48 on the valve face. Other inspection requirements were a strong joint and squareness of the top of the valve with the tube (to ensure correct final grinding).

Production rate was 80 assemblies per hour; annual production was only 1200 assemblies, too small a number to warrant mechanization. The cost of the induction brazing machine, which was used also on other projects, was $11,000. Labor cost per assembly was $0.0396, overhead was computed at 350% of labor cost, cost of flux and filler metal was $0.0420, for a total cost of $0.2202 — compared with $0.2385 per assembly for furnace brazing and subsequent induction hardening.

Several years of field experience demonstrated the reliability of the simultaneous operation; failures were zero. Additional process details for simultaneous induction brazing and hardening are given in the table with Fig. 7.



Power supply	25-kw vacuum-tube unit
Frequency	400 kHz
Filler metal	0.040-in. wire, BAg-1
Flux	AWS type 3A
Heating temperature (valve face)	1450 F
Heating time	30 sec
Postbraze heat treatment	375 F for 1 hr
Production rate	80 assemblies per hour
Total cost per assembly	$0.2202

Fig. 7. Pump valve-and-tube assembly that was induction brazed and surface hardened in one operation (Example 589)

Brazing of Dissimilar Metals

In addition to the differences in characteristics of dissimilar base metals that affect their brazeability by any process — namely, differences in thermal expansion, thermal conductivity, and compatibility with specific filler metals — differences in magnetic characteristics also have an effect in induction brazing.

Despite the above variables, induction brazing is used successfully for joining a number of other base metals to steel. There are at least two methods for dealing with the difference in heating rates. One is to design the assembly so that the component that is heated more easily has the larger mass, which acts as the larger heat sink and reduces the heating rate. Another method is to design the inductor so that the component that heats more easily is positioned in a weaker part of the magnetic field.

Sometimes, when other base metals are to be brazed to steel, a compromise must be made in selection of filler metal. For instance, BAg-1 is generally preferred for brazing one ferritic steel to another, but when austenitic stainless steel is one of the base metals, BAg-3 is a better choice, because it is suitable for both base metals.

Difference in coefficient of thermal expansion (and contraction) of the base metals will produce shear stress in the cooling joint. This stress must sometimes be accommodated to avoid cracking of the joint. Accommodation can be provided by placing a relatively thick, ductile metallic interlayer between the base metals, such as that obtained with a sandwich consisting of a fine, iron gauze between strips of filler metal. Another method is to use a ductile copper strip clad on both sides with filler metal, as in the example that follows.

Example 590. Use of a Filler-Metal "Sandwich" To Avoid Cracking of a Brazed Carbide-to-Steel Joint (Fig. 8)

To avoid cracking of brazed joints between tungsten carbide tips and tool shanks of low-carbon steel or tool steel, a "sandwich" brazing technique was used. Brazing was done with a 10-kHz, 25-kw machine. The assembly rested on a cemented-asbestos board through which the inductor penetrated, as shown in Fig. 8.

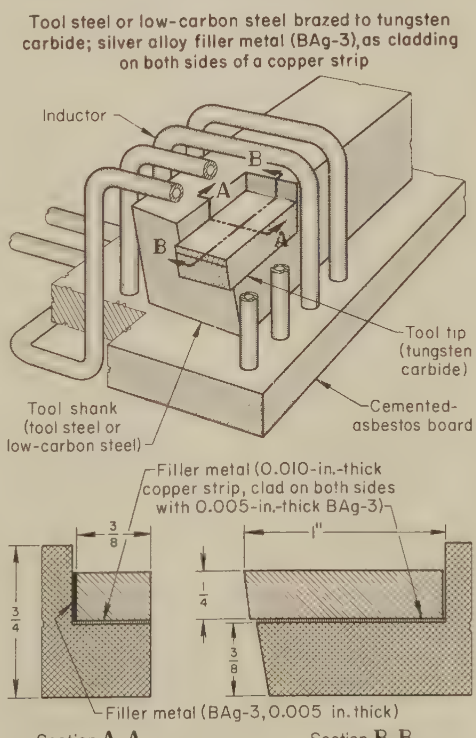


Fig. 8. Induction brazing of a carbide tip to a steel tool shank, using a filler-metal "sandwich" to prevent shear-stress cracking of the carbide (Example 590)

Those surfaces of the carbide tip to be brazed were prepared by grinding and those of the steel shank by machining and vapor degreasing.

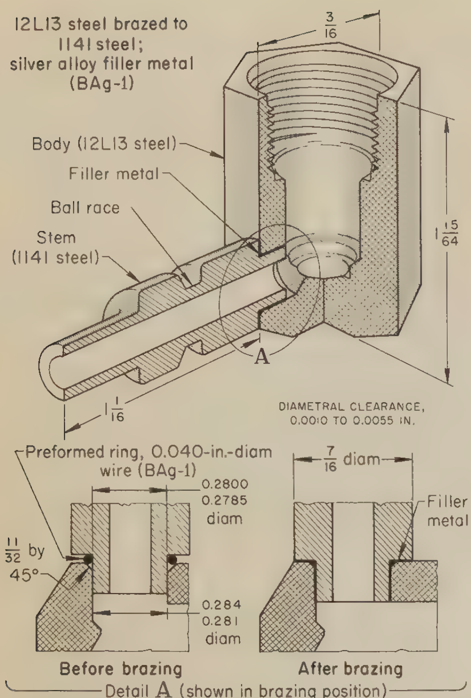
Filler metal for the portion of the joint between the bottom of the tip and the recess in the shank was a "sandwich" of 0.010-in.-thick copper strip, clad on both sides with 0.005 in. of BAg-3; filler metal for the vertical portion of the joint was a 0.005-in.-thick strip of BAg-3 (Fig. 8). The tip and shank were coated with flux and then assembled so that the tip rested on the filler-metal sandwich and also held the strip of solid filler metal against the sidewall of the recess.

The tip end of the assembly was inserted into the inductor only as far as the base of the tip to minimize the effect of the heat of brazing on the main portion of the shank. When the filler metal was melted, the tip was moved back and forth with a nonmetallic rod to puddle the filler metal, release gas bubbles and ensure good wetting. After brazing, the assembly was removed from the inductor, allowed to cool in still air, and then cleaned of flux.

The coefficients of thermal expansion of carbide and steel are different, causing the tip and shank to expand or shrink different amounts during heating to and cooling from the brazing temperature, which in turn produces a shear stress along the joint, sometimes large enough to crack it. The advantage of having the filler-metal sandwich beneath the tip was that the ductile copper yielded under the shear stress, allowing all components of the joint to remain firmly bonded.

Cost of Induction Brazements vs Forgings and Castings

If a part, ready for brazing, can be produced in an automatic bar machine, the brazed assembly will cost less than a similar part machined from a forging or a casting, provided that production quantities are sufficient to justify the cost of equipment for induction brazing. Hydraulic-actuator components,



Comparison of Direct Labor Costs

Forging	$0.040
Machining the forging	0.300
Total cost per fitting	$0.340
Machining two components before brazing	$0.160
Brazing	0.024
Total cost per fitting	$0.184
Saving per fitting by use of brazing	$0.156

Conditions for Induction Brazing

Power supply	25-kw vacuum-tube unit
Frequency	400 kHz
Filler metal	0.040-in. wire, BAg-1
Flux	AWS type 3A
Brazing temperature	1300 F, approx
Heating time	60 sec
Postbraze treatment	Induction harden race
Production with 6 inductors	125 fittings per hour
Annual production	36,000 fittings

Fig. 9. High-pressure fitting made as a brazed assembly of machined components instead of as a machined one-piece forging, to reduce cost (Example 591)

connectors, and pressure-line hardware are among the parts produced in automatic bar machines and assembled by induction brazing.

The example that follows describes an application in which cost was reduced by changing from a machined forging to a brazed assembly.

Example 591. Change From Forging to Induction Brazing That Reduced Labor Cost by 46% (Fig. 9)

Originally, the high-pressure fitting shown in Fig. 9 was made from 1117 steel by forging, machining, and carbonitriding all over (even though hardness was required only on the ball race). Direct labor cost for forging and machining was $0.34 per fitting.

Because the annual production requirement was 36,000 fittings, a lower-cost method was sought. The method was changed to the brazing together of a stem and a body produced in an automatic bar machine. The stem was made from 1141 steel because the ball race had to be hardened to Rockwell C 47 to 58 in a separate operation. The body of the fitting was made from 12L13 steel for ease of machining.

With the use of six inductors, supplied with power from a vacuum-tube unit and mounted on an insulated arm that could be swung over the assembled components, six assemblies were brazed simultaneously. Each inductor was a two-turn coil of 3/16-in.-OD copper tubing on a 1-in. diameter.

The components to be brazed were degreased, and then were assembled with a preformed ring of BAg-1 filler metal preplaced on the neck of each stem (Fig. 9). The preformed ring was located by a chamfer on the hole in the body. The diametral clearance in the joint was 0.0010 to 0.0055 in. After assembly, the joint surfaces, which were held apart by the filler-metal ring, were brushed with type 3A flux.

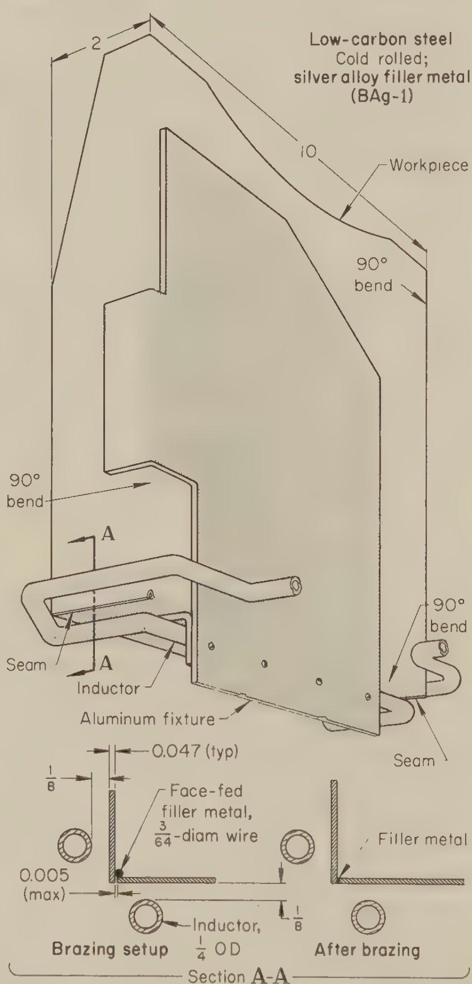
The assembly was placed in a positioning fixture, with the stem up. The inductor heated the assembly in 60 sec to approximately 1300 F. When the operator saw the filler metal emerge at the edge of the joint, he pressed each stem down firmly to seat it in the hole and to ensure that it was aligned and square. The assembly was allowed to cool in the positioning fixture until the filler metal solidified (approximately 1000 F). The brazed assembly was then removed with pliers and placed in a basket, for cooling to room temperature. Flux was removed by pickling and tumbling.

The races were subsequently heated to approximately 1500 F, by use of the induction brazing unit, and oil quenched. Heating in this operation was localized to prevent deformation at the brazed joint.

Cost of direct labor for machining and brazing was $0.184 compared with $0.340 for forging and machining. The difference in material costs for the two production methods was insignificant.

Each assembly was inspected visually and was required to show filler metal continuously around the joint. A gage check was also made to ensure that the two components were at right angles. Rejection rate was less than 2%.

Had it not entailed the purchase of a furnace, furnace brazing with copper alloy filler metal might have been used instead of induction brazing. (Furnace heating cannot be localized, but a copper brazed joint can withstand the 1500 F hardening temperature required for the ball race.) However, it was estimated that an annual output of 700,000 fittings (instead of 36,000) would be required to amortize the cost of a new furnace in three years.



Power supply	15-kw vacuum-tube unit
Frequency	450 kHz
Filler metal	0.047-in. wire, BAg-1
Flux	AWS type 3A
Heating time	12 sec
Production rate	77 trays per hour(a)
Rejection rate	Less than 1%(a)

(a) In torch brazing, the method previously used, production rate was only 29 trays per hour and rejection rate was 10%.

Fig. 10. Letter tray with two seams that were induction brazed, using the setup shown (Example 592)

Induction Brazing vs Alternative Joining Processes

Induction brazing is often a suitable alternative to other joining processes, depending largely on the size and shape of assembly and joint requirements.

In the four examples that follow, induction brazing replaced other joining processes for a variety of reasons. In the first and second of these examples, induction brazing replaced torch brazing and oxyacetylene welding, respectively. In the third example, induction brazing was used instead of shielded metal-arc welding of thin tubes. In the fourth example, distortion was reduced by changing to induction brazing from gas tungsten-arc welding.

Example 592. Use of Induction Instead of Torch Brazing (Fig. 10)

When torch brazing was used for joining the two seams on the open-end letter tray (the outside of which is shown in Fig. 10), the inside and outside of the brazed joints required careful cleaning and considerable grinding to obtain an acceptable finish. Also, one operator could braze only 29 trays per hour, and rejection rate was 10%.

To reduce the cost of excessive cleaning, grinding and rework, and to increase operator output, a change was made to induction brazing, with BAg-1 filler metal. This involved an investment of $12,000 for a vacuum-tube unit, $1700 for a heat exchanger, and $200 for two special inductors.

The inductors were formed from copper tubing. Water was circulated through the inductors and the power supply under pressure of 40 to 80 psi, and at a minimum rate of seven gallons per minute. To avoid condensation that might short circuit the inductor or power supply, cooling-water temperature was not allowed to fall below 70 F. This was done by circulating it through the heat exchanger. The coils of the inductor were specially shaped, as shown in Fig. 10, to concentrate heat at the joints. (For later production, inductors formed from round tubing were replaced with a pair made from 1/4-in.-square tubing and having mitered corners that fit the rectangular workpieces better and produced a more even heating pattern.) A fixture was constructed by bolting together two pieces of aluminum sheet that had been bent at right angles to support and locate the tray so as to give an air gap of 1/8 in.

The trays were formed from notched stock to a maximum clearance of 0.005 in. per joint, and the edges were wire brushed to remove burrs. The corners of the trays were then dipped in type 3A flux, and the trays were placed in the fixture, as shown in Fig. 10, and heated for 12 sec. When the

workpiece reached the flow temperature of the filler metal (approx 1150 F) and while the current was still flowing through the inductor, BAg-1 was face fed to a ¾-in. segment of each 2-in.-long joint; the remainder then filled by capillary action. Toxic fumes were removed by an exhaust.

After brazing, the trays were washed in a tank containing a 1-to-6 emulsion of soap and water, at 190 F, which removed 80 to 90% of the flux residue and also protected the trays from rusting. The brazed joints were then lightly sanded.

Two identical inductors were connected to one power supply. Thus the operator could load the fixture of one while the other was heating. In this way, 77 trays per hour were produced (compared with 29 by torch brazing). The rejection rate was less than 1% compared with 10% when torch brazing was used. Grinding and much of the cleanup and rework were eliminated. Cost of the induction brazing equipment was recovered in less than a year.

Quality was controlled by regular inspection of the appearance of the joints, and spot testing was carried out by pull tests on the corners.

Example 593. Change From Oxyacetylene Welding to Induction Brazing (Fig. 11)

Oxyacetylene welding was the method originally used to join low-carbon steel chair-back uprights, of 0.048-in.-wall, square, welded tubing 27¼ in. long, to low-carbon steel end caps ⅞ in. square by 0.060 in. thick. The welded joints had to be ground and polished, and many were rejected because of undercutting and porosity. Reject and rework rate was 10%. Hourly production per operator was 110 assemblies.

Induction brazing of five assemblies simultaneously in one inductor was selected to replace welding. Figure 11 shows the setup used. The power supply was a vacuum-tube unit, which operated on a 440-volt, three-phase, 60-Hz line. It had an output of 15 kw at a frequency of 450 kHz. The inductor, made of copper tubing, was arranged to accommodate five assemblies in a single turn and was shaped to heat at the joint surface and tilted to allow access to the fixture. Optimum air gap to the workpiece was about ⅛ in. The inductor and the power supply were cooled by water at a minimum rate of 7 gal per minute under pressure of 40 to 80 psi. A heat exchanger was used to keep the water temperature from falling below 70 F, to prevent condensation that might cause short circuits in the inductor and power supply.

The fixture consisted of a cemented-asbestos board on an aluminum support. It had ⅞-in. slots spaced about ½ in. apart to accommodate and locate five assemblies.

Five end caps were placed in the slots of the fixture and then a single strip of BAg-1 filler metal 0.005 in. thick by ¼ in. wide was laid over them in the position shown in Fig. 11. Each of the five uprights, which had been dipped first in trichlorethylene, to remove mill oil, and then in type 3A flux, was placed on the filler metal so that the filler metal was pressed between it and the end cap. The upper ends of the uprights were held by magnets.

When all five assemblies were in place, an induction heating cycle of 28 sec was started. Heating was greatest next to the upper (back) half turn of the inductor, so that when the filler metal melted (approx 1150 F), it flowed by capillary action toward the hottest part of the joint and filled the entire joint. While the filler metal was still molten, the end caps and the uprights were aligned manually with a short paddle made from cemented-asbestos board. (The inductor was lower in front of the work to allow access for the paddle.)

The brazed assemblies were washed in a tank containing a 1-to-6 emulsion of soap and water, at 190 F. This emulsion removed 80 to 90% of the flux residue and also acted as a rust inhibitor. The brazed joints were then lightly belt-sanded.

Quality was controlled by visual inspection. The rejection rate was less than 1%,

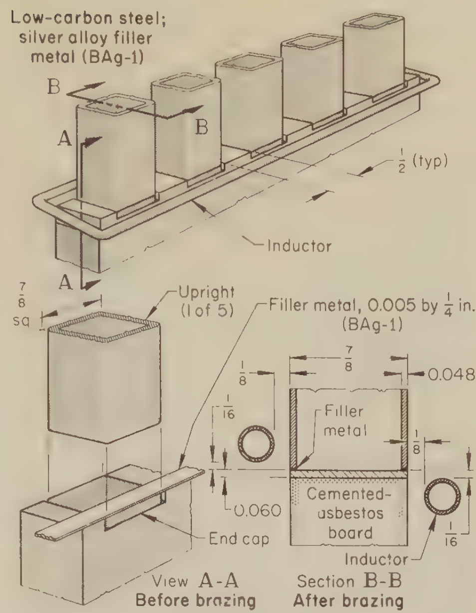


Fig. 11. Setup for induction brazing five chair-back uprights to five end caps at one time (Example 593)

as compared with 10% for oxyacetylene welding. Average production rate for one operator was 232 assemblies per hour — more than twice the rate for welding.

Example 594. Use of Induction Brazing Instead of Shielded Metal-Arc Welding (Fig. 12)

Originally, a 5⁄32-in.-wall resistance-welded and drawn low-carbon steel tube and a hot rolled 1045 steel collar were joined by shielded metal-arc welding. The joint design for welding is shown in Fig. 12. During welding, unintentional melt-through of the tube occurred occasionally. Moreover, the weld beads had to be ground for satisfactory appearance, and some of the welded joints cracked in service.

To improve the appearance of the joint and to increase strength, induction brazing was substituted for welding. Two joint designs were used for brazing, as shown in Fig. 12. In the first design, a single groove to take a preformed ring of filler-metal wire was machined in the collar, and the collar and tube were then threaded together. Before brazing, both parts were cleaned with trichlorethylene, and type 3A flux was brushed on the tube. Then a preformed ring of 1⁄16-in.-diam BAg-1 wire was inserted in the groove provided for it, and the parts were screwed together, mounted on centers and brazed using a 100-kw, 10-kHz power supply. The joint seemed strong, but in the field it failed by fatigue through the innermost thread.

In an improved joint design, the threads were eliminated and a second groove for filler metal was added. Filler metal for both grooves was 1⁄16-in.-diam BAg-1 wire, in preformed rings. Visual inspection after brazing showed a full perimeter of filler metal at both ends of the joint. The brazed assembly withstood an axial pull of 60,000 lb (equivalent to a shear stress of 30,000 psi), which was above service requirements. None of the assemblies that incorporated the improved joint design failed in service.

Brazing, employing the improved joint design, had the following advantages:

1. The assembly was stronger. The higher strength was attributed to the fact that, in the brazed joint, a large area of the joint between the collar and the tube was bonded, whereas in the welded joint, bonding was restricted to the collar ends.
2. Melt-through was eliminated.
3. The appearance of the joint was improved, and the grinding operation was eliminated.
4. Production rate was increased (see time comparison in the table with Fig. 12).

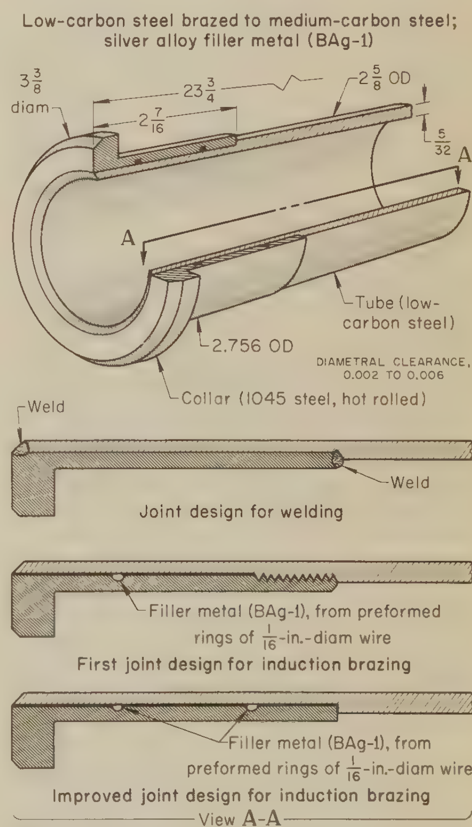
Example 595. Use of Induction Brazing Instead of Gas Tungsten-Arc Welding (Fig. 13)

An assembly of a component used in an air-operated pump was made by joining three parallel tubes, 13 5⁄16 in. long, to two machined end pieces (see Fig. 13).

Originally, the assembly was joined by gas tungsten-arc welding, but the difference in heat absorption by the tubes and the relatively massive end pieces caused excessive warping of the tubes. Because good alignment was necessary to prevent faulty operation of the pump, the tubes had to be straightened after welding. Cost for labor, including welding and straightening, was $0.847 per assembly.

Induction brazing, for which equipment was available, was selected to replace gas tungsten-arc welding. Brazing conditions are given in the table with Fig. 13. (The production quantity was too low for furnace brazing, and the cost of fixtures would have been too high.)

The inductor for the larger end piece (lower end piece in Fig. 13) was 2¼ in. long, had an inside diameter of 3¼ in. and was made of eight turns of ¼-in.-OD copper tubing. To prevent burning of the crests of the external threads on the end piece during the relatively long high-frequency heating, the heating of the threads was reduced by constructing the inductor in a manner to produce cancellation of the magnetic flux field in this area. This was done by winding the four turns on one end of the inductor in the direction opposite to that of the other four turns. The inductor for the smaller end piece (upper



Item	Welding	Brazing(a)

Joining time, hr	3.66(b)	2.37(c)
Total time, hr	3.86	3.17

(a) Using improved design shown. (b) 0.122 hr per assembly. (c) 0.079 hr per assembly.

Fig. 12. Tube-and-collar assembly in which brazing replaced welding, with appropriate changes in joint design (Example 594)

end piece in Fig. 13) was 2 in. long, had an inside diameter of 2⅝ in. and was made of four turns of ¼-in.-OD copper tubing. (The smaller end piece had no external threads and the inductor was wound without reverse turns.)

A special fixture, consisting of a base, an alignment bar, and two mounting plugs having threads that matched those of the end pieces, was used. This fixture had been designed to meet the following requirements: (*a*) allow room for the inductor, (*b*) hold the end pieces parallel and square with each other and square with the centerline within 0.004 in. TIR, and (*c*) hold the pitch diameters of the threads of the end pieces concentric within 0.010 in. TIR.

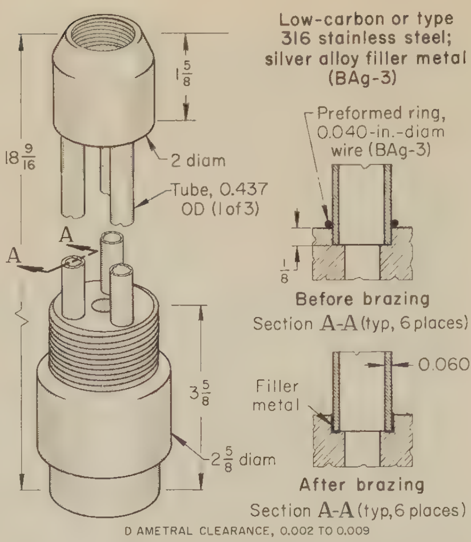
The tubes and end pieces were electrocleaned, pickled in hydrochloric acid, and electropolished. The tubes were dipped in type 3A flux, and preformed rings of 0.040-in.-diam BAg-3 filler-metal wire were slipped over them. (BAg-1 was not used, except in emergency, because it did not consistently make satisfactory fillets on stainless steel. Filler metal BAg-3 is generally preferred for brazing stainless steel and is satisfactory for brazing carbon steel.)

For rapid production, only one end was brazed in each production run. First, the large end piece was mounted on the fixture base, and the tubes and filler-metal rings were positioned. A mounting plug was screwed into the small end piece. Then the alignment bar was inserted through the plug (and end piece), the cluster of tubes and the large end piece, and was fastened in the fixture base. The inductor was turned on for approximately 138 sec, heating the joint to 1300 to 1375 F. The inductor was shut off by a timer, and the sub-brazement was removed from the fixture.

Then, in a separate operation, the small end piece was mounted on the fixture base, and the sub-brazement and filler-metal wire were positioned. A mounting plug was screwed over the large end piece. Then the alignment bar was inserted through the plug (and sub-brazement) and the small end piece, and was fastened in the fixture base. The brazing procedure was the same as for the other end; after brazing, flux was removed by rinsing and pickling.

The brazed assemblies were given 100% inspection, which included visual examination for proper joint fill and fillet, a gage check of alignment of faces and threads, and a hydrostatic pressure test at 800 psi when the assembly was installed in the pump. Rejection rate for the brazed assemblies was less than 1%. The brazed assemblies could be incorporated into the pumps without additional straightening.

Production rate was 13 assemblies per hour — or three assemblies per hour more than had been joined by gas tungsten-arc welding. Labor cost per piece for brazing was 70% of that for welding and straightening.



Power supply	25-kw vacuum-tube unit
Frequency	400 kHz
Brazing temperature	1300 to 1375 F
Heating time, each 3-joint end	2.3 min
Production rate	13 assemblies per hour
Labor cost per assembly	$0.592

Fig. 13. Pump-part assembly, induction brazed to minimize distortion (Example 595)

Two-Process Brazing. In the preceding example, two sets of joints in the same assembly were successively induction brazed in two stages. For some assemblies that incorporate two joints, it may be advantageous to use induction brazing for one joint and furnace brazing for the other joint. This sequence was employed in the next example.

Example 596. Use of Furnace and Induction Brazing for Different Joints in the Same Assembly (Fig. 14)

A housing-cover assembly for an automotive brake booster was fabricated by fastening a machined ferrule to one end of a welded tube and a press-formed cover to the other end, as shown in Fig. 14. The ferrule was made of cold rolled 1112 or 1113 steel; the tube and cover, of 1010.

The ferrule-to-tube joint (detail B in Fig. 14) lent itself to brazing in a controlled-atmosphere furnace, which was available in the plant. The cover-to-tube joint (detail A in Fig. 14) was subsequently brazed by induction, because the close final dimensions necessary could not be held in furnace brazing, and brazing in a furnace would distort the press-formed cover.

Before being furnace brazed, the ferrule and tube were spray cleaned with a hot alkaline solution and then assembled in an arbor press. The joint was designed for a press fit, with the 1.721-to-1.724-in. outside diameter of the ferrule joint surface and the 1.710-to-1.720-in. inside diameter of the tube producing interference of 0.001 to 0.014 in. A proprietary flux was brushed on the surfaces surrounding the joint, because the furnace atmosphere was not highly reducing, and a preformed ring of BCu-1 filler-metal wire was dropped into place inside the tube. The assemblies were then loaded, ferrule end down, onto graphite plates. The plates were subsequently loaded onto trays, 70 assemblies to a tray, and furnace brazed (for conditions, see table with Fig. 14).

For induction brazing, the subassembly was loaded over a locator-clamp in the induction brazing fixture (Fig. 14). In automatic sequence, this locator-clamp expanded and was drawn down to clamp the subassembly firmly in position.

The cover was spray cleaned with a hot alkaline solution, type 3A flux was brushed inside the hole, and a preformed ring of BAg-1 filler-metal wire was set in place inside the hole. The cover was then put into the fixture and over the tube, and four locator posts on the fixture were inserted into four mounting holes in the cover (see Fig. 14). The joint was designed for a press fit to accommodate the tolerance of the tubing as-purchased, the 1.808-to-1.813-in. outside diameter of the tube and the 1.801-to-1.806-in. inside diameter of the cover at the joint producing a room-temperature interference of 0.002 to 0.012 in. (Differential expansion of tube and cover during heating allowed the filler metal to flow through the joint.)

Pressing two palm buttons started the following automatic sequence. The piston of a bottom air cylinder drew down the locator-clamp, expanding it and clamping the ferrule. The piston of a top air cylinder pushed the clamping plate down, which pressed the cover down onto the tube and the four locator posts, thus holding the 4.174-in. dimension between the cover and the flange on the ferrule. Heating time was 6 sec, followed by a 5-sec cooling air blast. The piston of the bottom cylinder pushed up the locator-clamp, releasing the ferrule, and then the piston of the top cylinder and the clamping plate retracted, releasing the cover. The assembly was unloaded by hand and cleaned of flux.

The single-turn inductor was positioned ⅛ in. below the cover; the gap between cover lip and inductor was 0.090 in.

Other Examples of Induction Brazing in This Volume

For information on induction brazing of other metals, see Examples 628 and 629 (stainless steel) and Examples 649 to 654 (copper alloys).

Resistance Brazing

RESISTANCE BRAZING is a resistance joining process in which the workpieces are heated locally and filler metal preplaced between them is melted by the heat obtained from resistance to the flow of electric current through the electrodes and the work. In the usual application of the process, the heating current is passed through the joint itself. Resistance welding equipment is used, and the pressure needed for establishing electrical contact across the joint is ordinarily applied through the electrodes. The electrode pressure also is the usual means for providing the tight fit needed for capillary behavior in the joint. The heat for resistance brazing can be generated mainly in the workpieces themselves, in the electrodes, or in both, depending on their electrical resistivity and dimensions.

Applicability. Parts of many different shapes can be resistance brazed, provided that the surfaces to be joined either are flat or conform over a sufficient contact area, and that they can be held together under pressure to permit the heating current to flow through the joint, and the filler metal to be distributed throughout the joint by capillary action. Workpieces that can be joined by resistance brazing range from wire 0.001 to 0.005 in. in diameter to assemblies having joint areas of about 10 to 15 sq in. Joint area in most high-production resistance brazing is small, usually not more than 0.1 to 0.6 sq in.

The use of portable welding heads or tongs permits resistance brazing to massive parts or structures and in locations inaccessible to standard resistance welding machines.

The process is used where the workpieces must be heated locally and maximum local temperatures must be below the melting point of the workpieces. In some applications, total heat input can be sufficiently small and localized to make joints for which conventional arc or resistance welding or other brazing methods are not suitable (see Preventing Overheating, page 653, and Examples 598, 602, 603 and 604). Filler metals that flow at 1100 to 1500 F are used in resistance brazing of most common metals.

Resistance brazing can produce joints that have bond areas many times as large as those of resistance spot or seam welds, and that have correspondingly greater strength. When resistance brazing is done in resistance welding machines, joining can be done at high production rates, at low labor cost, and with low operator skill.

Metals Joined. The work metal most frequently joined by resistance brazing is copper. Resistance brazing with high-resistivity electrodes or electrode facings is an efficient method of providing localized heating at the joint in this highly conductive metal, while avoiding fusion of the copper base metal. In addition, copper is the only commonly used metal that can be brazed in air with self-fluxing filler metals (copper-phosphorus alloys, BCuP type), and thus without the use of a flux.

The workpieces were made of copper in 12 of the 16 examples of resistance brazing in this volume, and in two other examples, one of the two workpieces was copper; BCuP-5 was used as a filler metal in 11 of the 14 examples in which copper was a work metal.

The metals that rank next in frequency of joining by resistance brazing are copper alloys. Copper alloy 184 (chromium copper) was one of the work metals in Example 606, and the difficult-to-weld copper alloys 360 (free-cutting brass) and 353 (high-leaded brass, 62%) were joined in Example 602. Copper alloys (and copper) have been resistance brazed in producing a variety of assemblies used in circuit breakers, electrical switchgear, and power-distribution equipment.

Electrical contacts made of silver, silver-graphite and silver-molybdenum have been resistance brazed to copper in making heavy-duty circuit breakers and other types of electrical equipment, in an important application of the process.

Steel was the work metal in Example 601 in this article, and was one of the two work metals in Example 660 in the article on Brazing of Copper Alloys. In plants where copper and copper alloy assemblies are resistance brazed, the process occasionally is applied also to assemblies made of steel or other metals. Typical resistance brazed low-carbon steel assemblies made in one such plant in quantities of 300 to 400 per year were transformer brackets made by joining hat-shape strips ⅛ in. thick by 1 in. wide to flat strips ⅛ by 1 by 6 in., making a 1-in.-square joint at each end of the flat strip with the aid of preplaced foil of BAg-1a filler metal.

Fins made of steel or other metals have been resistance brazed to low-carbon steel tubing for heat exchangers.

Stainless steel, nickel alloys, and aluminum are resistance brazed to a limited extent, and occasional use of the process has been made on other metals. Stainless steel internal baffle plates have been resistance brazed to the inner walls of 1020 steel tubes in heat-exchanger applications.

Equipment

Resistance brazing ordinarily is done with conventional resistance welding equipment as described in the article on Resistance Spot Welding. This equipment can be used for some resistance brazing applications without modification. Generally, however, heating and cooling times are longer and electrode force is lower for resistance brazing than for resistance spot welding. Resistance spot welding machines may be modified to provide ranges of operating conditions suitable for resistance brazing, or machines may be designed especially for resistance brazing. Other changes often needed to adapt resistance spot welding equipment for resistance brazing are in electrode holders and electrodes. Electrode holders that provide low inertia and fast follow-up are sometimes needed (see Use of Fast Follow-Up, page 651, and Examples 602 and 603).

Adaptation for high-volume production is generally the same as in resistance spot or projection welding, except for the additional need in most resistance brazing applications of providing for the preplacement of filler metal and, sometimes, flux in the joint.

Power sources for most resistance brazing are conventional resistance welding transformers, which deliver low-voltage, high-amperage power (see page 405 in the article on Resistance Spot Welding). A higher voltage is usually needed in the secondary circuit in resistance brazing than in resistance welding, especially when using high-resistance electrodes, and hence the transformer should have a relatively high kilovolt-ampere rating.

Capacitors or capacitor banks can be used as power sources for resistance brazing of wires or other small parts in joints for which the heat input must be extremely small and the heating time very short. Before each operation, the capacitors are charged with direct current from either a rectifier or a motor-generator (see page 475).

A capacitor was used as the power source for resistance brazing individual copper connector wires 0.002 to 0.005 in. in diameter to copper terminals clad with BCuP-5 brazing alloy in Example 603, discharging 2 to 3 watt-seconds of energy in a heating time of 2 to 3 milliseconds. A capacitor also was used for resistance brazing braided copper connector wires (each consisting of eight strands of 0.005-in.-diam wire) to high-carbon steel terminals electroplated with silver over copper, in Example 660 in the article on Brazing of Copper Alloys.

Controls for resistance brazing are the same as for resistance spot and projection welding (see page 402 in the article on Resistance Spot Welding). Brazing current, electrode force and timing usually are controlled automatically. Slope control and pulsing, where needed, can be programed into the machine. Electrode advance and retraction, and sequencing of some or all machine functions, can be done manually or automatically.

Fixed timing is sometimes unsatisfactory because it does not provide

This article has been prepared from contributions of members of the Committee on Welding and Brazing of Copper and Copper Alloys and the Committee on Brazing of Steel. Several of the examples were contributed by members of other Metals Handbook committees on welding and brazing.

compensation for variations in heat input to the joint from the electrodes or in the heat-sink capacity of workpieces, fixtures and other equipment during continuous production runs. Automatic termination of heating by a controller that senses temperature at or near the joint can provide uniform heating of the joint and filler metal, regardless of variation in heat input or heat loss, as in the next example.

Example 597. Use of an Infrared Sensor for Control of Heating for Automatic Resistance Brazing (Fig. 1)

The assembly shown in Fig. 1, a connector for an electric controller, was composed of a U-shape copper-strip contact finger brazed to a lug consisting of a short length of copper tubing that was flattened at the joint. No cleaning was necessary before brazing, because both members of the assembly had been tin plated.

Erratic joint strength was observed in the first production runs, in which the assemblies were joined by induction brazing. When the joining process was changed to resistance brazing to improve consistency of joint strength, it was necessary to adjust the heating time during continuous production runs to compensate for progressive heat buildup in the electrodes. Timing was accurate to within one cycle ($\frac{1}{60}$ sec).

The need for periodic adjustment of the heating time to obtain consistent joint strength was eliminated by changing from a time-control method of regulating heating to a method in which heating was automatically terminated by a controller actuated by an infrared photocell that sensed the work temperature near the joint. The sensor was sighted on the contact finger at the point shown in Fig. 1.

The filler-metal preform (see section A-A in Fig. 1) was a 0.63-in. square of 0.005-in.-thick BCuP-5. This filler metal, self-fluxing on copper, was selected to avoid the need for using a separate flux. In spite of the relatively low electrical conductivity (10% IACS) of BCuP-5, electrical resistance across the joint area (about 0.4 sq in.) was low enough in relation to the small current load (100 amp, max) carried by the connector in service. The machine used for brazing was a 75-kva, air-operated, press-type resistance welding machine. The electrodes had RWMA class 2 (chromium copper) shanks and class 14 (molybdenum) faces. The force applied to the electrodes was 350 lb. The brazing current was 18,000 amp and the brazing time averaged 50 cycles, or slightly less than 1 sec. Alignment of the workpieces was maintained by asbestos fixtures (not shown in Fig. 1).

The operator loaded the contact finger into the fixture, placed the filler-metal preform in position, placed the lug on top of the filler metal, and pushed the start button to close the electrodes and actuate the brazing sequence, which was completed without further attention by the operator.

Quality was controlled by random checks on the operation and the brazed assemblies. In addition to visual examination of the completed joints for presence of a fillet, randomly selected brazed assemblies were tested to destruction in a pull test. The brazed joint was required to remain intact in the destructive test. Equipment details and brazing conditions are given in the table that accompanies Fig. 1.

Machine Construction. The machines used for resistance brazing, which generally are conventional resistance welding machines, are ordinarily of press-type construction (see page 406 in the article on Resistance Spot Welding), in which the upper electrode and welding head move in a straight line and thus assist in maintaining alignment of the workpieces during brazing.

Machines for intermediate to high production are usually floor-standing or bench-mounted air-operated types, as in 12 of the 16 examples of resistance brazing in this article and in the article on Brazing of Copper Alloys.

Portable machines, although ordinarily rated for lighter duty than floor-standing or bench-mounted machines, may have the same capabilities in all other respects (see page 406 in the article on Resistance Spot Welding). The portable head can be of a size suitable for use in close quarters and for carriage mounting in applications where the brazing head must travel. In the example that follows, resistance brazing with a carriage-mounted welding head was combined with other assembly operations in a manufacturing line.

Example 598. Incorporation of Cross-Wire Resistance Brazing Into a Mechanized Coil-Winding Operation (Fig. 2)

The 36-to-48-in.-long coil shown under construction in Fig. 2 was used to read out positions of machine-tool components on a numerically controlled machine tool. For this purpose, precisely located tap leads were brazed to the coil wire at predetermined intervals in a straight line along the coil. As many as 48 taps were made on a single coil, and in order to ensure the precision of the readout, the taps had to be located within ± 0.003 in. of true position.

Flexible wires for the tap leads were resistance brazed to the coil wire in cross-wire joints while the coil was being wound. For this purpose, a portable resistance welding head was mounted to the winding machine in such a way that it could move along the 36-to-48-in.-long coil into position for attaching each tap lead. The electrodes were $\frac{1}{4}$-in.-diam molybdenum rods that were grooved — the lower one to take the coil wire, and the upper one at right angles to the lower groove to accommodate the tap lead. (See detail A in Fig. 2.)

Both wires were of tinned copper corresponding to ASTM B3 — soft or annealed copper wire for electrical purposes, which ordinarily is alloy 110 (ETP copper) or low-resistance lake copper. The thickness of the tin coating was about 30 to 50 micro-in.

The coil wire was a single strand 0.032 in. in diameter; the tap-lead wire consisted of ten strands of copper, each 0.010 in. in diameter, and was covered with a plastic insulating coating. The insulation was manually stripped from the joint area at the end of the stranded tap-lead wire before brazing.

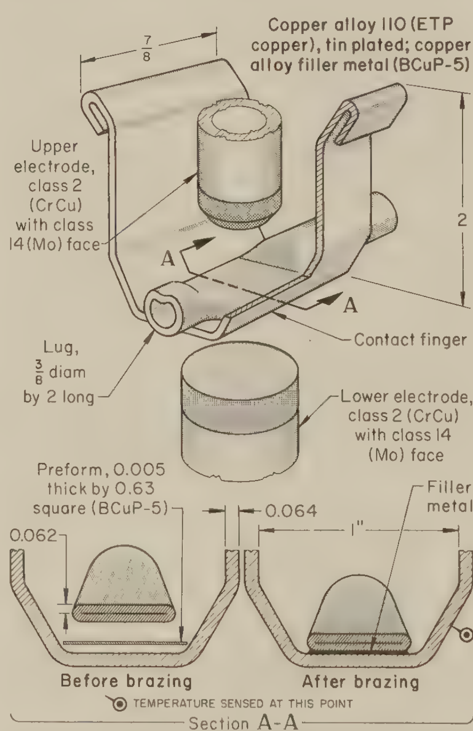
The BCuP-5 filler metal was furnished in strip 0.030 in. wide by 0.005 in. thick. Because the workpieces were tinned, the joint surfaces did not need cleaning, and because of the phosphorus in the filler metal, they did not need fluxing. The wires and the filler metal were furnished on spools, from which they were fed during production of the coils.

In operation, the operator pushed a button, and the coil-winding machine automatically wound the correct number of turns of coil wire onto the threaded insulating core. The coil wire from the spool was guided between the electrodes by a grooved phenolic plate. The operator drew the filler-metal strip, which was guided by a groove in the filler-metal guide, across the coil wire, stripped the insulation from the end of the tap-lead wire and laid the bare end over the filler-metal strip so that the tap-lead wire lay in its guide groove. A gage at the end of the guide for the tap-lead wire indicated the proper cutoff length (see detail A in Fig. 2).

At the press of a button, the electrodes closed and the joint was brazed. Timing of the brazing sequence was controlled by a solid-state timing device. Each joint was made at a point on the coil wire exactly one turn away from its final position. The filler metal and the tap-lead wires were trimmed by hand, and the final turn was made manually to bring the tap lead into final position on the coil. The operator inspected the joint, trimmed the excess tap-lead wire at the joint at the proper angle (75° from horizontal), placed a polyester insulating strip between the tap lead and the adjacent turn of the coil to avoid shorting that would give false readouts, and bent the tap lead to fit closely against the body of the coil. (Detail B in Fig. 2 shows completed assemblies of tap leads to a coil wire; detail C in Fig. 2 shows the setup for brazing and the assembly after brazing and trimming and after insulating and bending.) The operator then placed the end portion of the tap lead in a spring-type retaining fixture mounted on a circular disk (shown at right in the top view in Fig. 2) that was temporarily attached to the end of the coil core for holding the brazed tap leads during the remainder of the operation.

Joints had to be 100% sound in order to be electrically efficient. Five sample joints were made by the operator before the start of each coil, at the beginning of each shift, and after any interruption of about 1 hr in production, for machine qualification. The sample joints were checked visually for the presence of fillets, and joint strength was measured on each in a pull test. The mean breaking load for the five specimens had to be 24.3 lb min, and the range could not exceed 5.75 lb.

Production was not started (or resumed after an interruption) until acceptable test results were obtained. Making and evaluating the sample joints took about 5 min. During production, brazed joints were spot



Machine	Press-type, air-operated, 75-kva automatic resistance welding machine
Loading and unloading	Manual
Filler metal	BCuP-5, 0.005-in.-thick preforms

Hold time	40 cycles
Fixtures	Asbestos, for alignment of workpieces

Fig. 1 Electrical-connector assembly that was automatic resistance brazed using an infrared sensor to control heating time (Example 597)

checked visually for the presence of fillets. Rejects for quality of brazed joints averaged about 1%. Rejects for faulty positioning were negligible.

Resistance brazing was preferred to a mechanical attachment technique, which had been tried on prototype coils, because of the greater reliability of brazed connections and because of production problems anticipated for the mechanical technique. Attaching the tap leads by welding would have required higher temperatures, with the likelihood of burning the small strands of the tap-lead wire; soldering would have produced weaker joints with a lower operating-temperature limit in service. Equipment details and brazing conditions are given in the table that accompanies Fig. 2.

Hand-Held Tongs. A simpler type of portable resistance brazing machine is equipped with hand-held tongs that can be used conveniently to make brazed connections on massive assemblies that cannot be brought to a conventional resistance welding machine.

In the most rudimentary form, the hand-held current-carrying tongs, with electrodes attached at the end of each arm, are squeezed together by the operator to exert pressure on the electrodes and the work, and the current is turned on and off and adjusted manually by the operator. The amount of current passed through the joint, the duration of heating and the repetition rate may make it necessary to water cool the flexible current-carrying cables that connect the tongs to the power source (usually a conventional resistance welding transformer), and the tongs may also be water cooled.

Except for the very lightest units, the tongs or portable welding gun is suspended from an adjustable counterbalancing unit for convenient manipulation by the operator. The electrode force on most units is applied by air pressure, and a hydraulic booster is sometimes used. The tongs or welding gun can be constructed so that the electrode force is applied in a straight line, to avoid disturbing the alignment of the workpieces during the brazing operation.

In Example 658 in the article on Brazing of Copper Alloys, water-cooled hand-held tongs and water-cooled cables were used in resistance brazing copper connections to terminals in electrical equipment. In Example 659 in the same article, water-cooled tongs and cables were used in resistance brazing 0.098-by-8-in.-wide strip to ¼-by-4-in. bus bar. However, water-cooling equipment was not used in resistance brazing 0.010-by-1¾-in.-wide strip to 0.012-by-½-in. bus bar in the same example; in this application, overlapping multiple spot brazes were made, with electrode contact areas of 1 sq in. and 0.11 sq in., respectively. In Example 604 in the present article, water-cooled tongs and cables were used in resistance spot brazing patches on the inner conductor tube of ocean cable.

Metal Electrodes

Selection of electrode material for resistance brazing depends on the electrical conductivity of the work metal or work metals to be joined, the design and dimensions of the joint, appearance requirements for the brazed product, susceptibility of the work metal to

damage or marking, pressure needed on the work, production quantity of brazed joints, and cost of reconditioning or replacing an electrode.

Usual Materials. Electrodes for resistance brazing usually are made either of the standard electrode materials used in resistance spot welding, or of carbon. Low-resistivity metallic electrodes can be used for resistance brazing metals that have high to moderate resistivity; electrodes or facings made of highly resistive materials must be used for brazing low-resistivity metals. In the former instance, most of the heat for brazing is generated within the workpieces; in the latter, most of the heat is generated within the electrodes and is conducted to the work.

The materials used most frequently in resistance brazing are RWMA class 2 (chromium copper), RWMA class 14 (molybdenum), and various grades of carbon-graphite and graphite. Other standard and special electrode materials are sometimes used for special applications. Properties of the standard metallic electrode materials are given in Tables 2 and 3 in the article on Resistance Spot Welding (see page 409).

Class 2 (Chromium Copper). Electrode holders and shanks of faced electrodes for resistance brazing are usually made of RWMA class 2 material (chro-

Table 1. Properties of Five Carbon Electrode Materials Used in Resistance Brazing

Electrographite, oxidation resistant(b)	0.00042	50	2500	1.75

(a) This type of carbon electrode material is also commonly used in air carbon-arc cutting, as described on page 301 in Volume 4 of this Handbook. (b) Similar to the electrode material listed immediately above, but impregnated with a small percentage of an oxidation retardant, usually an inorganic compound containing boron or phosphorus, for longer life.

mium copper), which is a general-purpose resistance welding electrode material with a minimum electrical conductivity of about 75% IACS.

Class 2 electrodes usually are used for resistance brazing of work metals that have high to moderate electrical resistivity, because sufficient heat for brazing can be generated in the work metal itself. In Example 602, class 2 electrodes were used to permit localized heating in the joint and the use of a small total heat input in joining copper alloys 360 (free-cutting brass) and 353 (high-leaded brass, 62%), each of which has an electrical conductivity of 26% IACS. For resistance brazing low-carbon steel parts in Example 601, a class 2 upper electrode with a class 14 (molybdenum) facing was used to augment the heat generated in the workpieces. To avoid excessive heating in the lower workpiece, to which a fiber gear was attached, the lower electrode was class 2 without a facing.

Refractory Metal Electrodes. Class 14 (molybdenum) is intermediate in mechanical and electrical properties among the refractory metal electrode materials, and has a nominal electrical conductivity of 30% IACS. This material and class 13 (tungsten), because of their resistance to high temperatures and their nonsticking characteristics, are the only common electrode materials that have long life in resistance brazing of copper and other highly conductive nonferrous metals. They are about equal in electrical conductivity.

Class 14 (molybdenum) is generally preferred because class 13 (tungsten) is harder to machine and is likely to develop radial cracks in service. For reasons of economy, it is common practice, where applicable, to use facings, buttons or inserts of the refractory metal instead of making the entire electrode of the refractory metal.

Class 14 (molybdenum) electrodes were used in resistance brazing copper parts in Example 598 in this article and in Examples 655, 656 and 657 in the article on Brazing of Copper Alloys. Class 14 facings were used on class 2 (chromium copper) electrode shanks in resistance brazing copper parts in Examples 597 and 605 in this article, and in Example 658 in the article on Brazing of Copper Alloys.

Class 13 (tungsten) electrodes were used in high-speed resistance brazing of braided copper wire to high-carbon steel that had been plated with silver over an undercoat of copper in Example 660 in the article on Brazing of Copper Alloys. In this application, an electrode material with fairly low conductivity, reasonably good mechanical properties, and resistance to wetting by and alloying with silver or copper was needed; class 13 (tungsten) electrodes had a low wear rate when used to exert a force of 8 lb on the braided wire.

Special electrode materials are sometimes needed to meet the unusual requirements of specific resistance brazing applications. In Example 603 in the present article, an electrode made of 60Pt-40Rh was used to provide long life in high-speed mass-production resistance brazing of insulated copper wires to copper terminal pads clad with BCuP-5. In this application, the electrode had to withstand (*a*) the heating that was used for melting the polyurethane insulation on the copper wire, (*b*) contact with molten BCuP-5 filler metal, and (*c*) heating in air that was used for burning off insulation residues after each brazed connection was made. The electrode reached a temperature of 1700 F. (This electrode was manufactured by percussion welding, as described in Example 177.)

Carbon Electrodes

Carbon electrodes used in resistance brazing ordinarily are of two general types — carbon-graphite and electrographite (artificial graphite). These electrode materials are made by simultaneously heating and blending the finely divided raw materials with coal tar pitch, which serves as a binder.

The stock from which resistance brazing electrodes are made comprises a few of the many grades of carbon stock that are manufactured primarily for use in casting ferrous and nonferrous metals. When they are used as resistance brazing electrodes, their very high electrical resistivity, which is much higher than that of the commonly used metallic resistance brazing electrode materials (classes 2 and 14), permits the generation of a larger quantity of resistive heat than do the metallic electrode materials. Accordingly, carbon electrodes are used chiefly in resistance brazing of copper and other highly conductive (low-resistivity) work metals. They are less expensive than metallic electrodes in raw-material cost and fabrication cost, but wear more rapidly, oxidize in air at operating temperatures (red heat), and cannot withstand pressures as high as those used on metallic electrodes. Thus the use of carbon electrodes in resistance brazing is restricted to brazing of small quantities of parts for which low electrode pressure is satisfactory.

Composition and properties of the commercial carbon electrode materials vary, and there are no generally accepted industry standards and terminology. The properties of five grades that are generally typical of the materials used in carbon electrodes for resistance brazing are given in Table 1.

Carbon-Graphite. The first three types of electrode materials listed in Table 1 are called carbon-graphite, and are made from mixtures of finely ground petroleum coke (carbon) and natural or artificial (electro) graphite with coal tar pitch. They are extruded in suitable shapes and heated in an electric furnace at about 1500 F to give them the desired properties shown in Table 1. The heating converts about half of the pitch to carbon, and the remainder is driven off as gases.

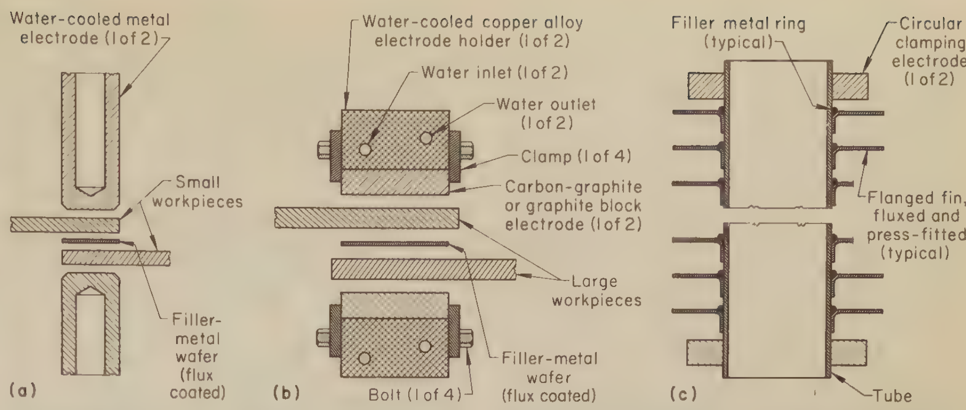
The final properties can be varied from those shown by changing the proportions of the raw materials, the particle size, and the time and temperature of heating. Increasing the ratio of graphite to carbon in the mixture, prolonging the heating time or increasing the temperature will lower resistivity, hardness and strength. Density is influenced chiefly by particle size.

Oxidation resistance of some grades of carbon-graphite is improved, for longer electrode life, by impregnating the cured material with a small percentage of an oxidation retardant, which is usually an inorganic compound that contains boron or phosphorus. In Table 1, oxidation-resistant grades 2 and 5 are the same as grades 1 and 4, respectively, except for the presence of an additive of this type.

Electrographite electrode material is made in the same way as the carbon-graphite grades, except that the extruded mixture of raw materials is heated at about 4500 to 4900 F, thus converting it to graphite (called artificial graphite or electrographite). Properties of a representative material of this type are given in Table 1, along with those of an oxidation-resistant or long-life impregnated form of the same material. Resistivity, hardness and flexural strength of electrographite electrode materials are substantially lower than for the hard carbon-graphite electrode materials.

Selection of Carbon Electrode Material. The general types of carbon electrode material shown in Table 1 (carbon-graphite and electrographite) have almost completely replaced the formerly used "straight carbon" types, which are made by heating finely ground petroleum coke and a binder at about 1500 F. The straight carbon grades typically have an electrical resistivity of about 0.0020 ohm-in. and a scleroscope hardness of about 100, and machining of these materials is much more difficult and costly than is machining of carbon-graphite and electrographite.

The hard carbon-graphite types are general-purpose materials and are preferred for most resistance brazing done with carbon electrodes, as brazing temperatures can be reached with less current than when the less resistive electrographite types are used. Electrographite is preferred for resistance brazing of metals that have a high surface resistance, particularly when one of the metals being joined is steel or another iron-base alloy. Soft carbon-graphite material combines high heating capacity with a low tendency to



Arrangements for resistance brazing of (a) *small flat parts using opposed water-cooled metal electrodes (conventional resistance welding type),* (b) *large flat parts using opposed carbon block electrodes attached to water-cooled copper alloy electrode holders, and* (c) *flanged fins to a tube using circular clamping electrodes*

produce local hot spots on the work metal, but has comparatively low wear resistance.

In resistance brazing with carbon electrodes, nonuniform current flow and resultant local overheating of the electrodes can shorten electrode life excessively. To prevent this, carbon electrodes must be tightly fitted into matching tapered adapters or clamped securely to the electrode holder, making contact with the holder over as large an area as possible, and provision must be made for adequate flow of cooling water in the electrode holder. Also, some carbon brazing electrodes are electroplated or sprayed with a copper coating about 0.002 in. in thickness, to reduce contact resistance against the electrode holder and to minimize internal temperature buildup in the carbon electrode.

The first and fourth grades in Table 1 are the same types of material commonly used in air carbon-arc cutting, as described on page 301 in Volume 4 of this Handbook.

Carbon electrodes were used in resistance brazing copper parts in Examples 599, 600 and 606 in this article, and in Example 659 in the article on Brazing of Copper Alloys. Hard carbon-graphite blocks were used in Example 599; electrographite blocks, in Example 600; and medium-hard carbon-graphite electrodes (having a resistivity of 0.0005 ohm-in.) in Example 606.

In resistance brazing with hand-held tongs in Example 659, 1-in.-square carbon-graphite electrodes were used with water-cooled tongs, while ⅜-in.-diam electrodes of the same material (which were used without water cooling) were coated with copper for longer life and to improve contact between electrode and electrode holder.

All four of the examples of resistance brazing with carbon electrodes were low-production applications where relatively rapid wear of electrodes, as compared with normal wear of metallic electrodes, could be tolerated.

Design of Electrodes

Commercially available resistance spot welding electrodes are used where the design and dimensions of workpiece and joint permit. The electrode tip is machined where necessary to provide a tip shape and face dimensions suitable for the work.

Carbon electrodes, depending on the size and design of the work, are in the shape of either standard metallic electrodes or flat blocks that may be several inches in length and width (size is usually limited by ability to obtain uniform heating and water cooling, or by the current capacity of the power source). When a high-resistance or long-wearing electrode material is required, it is often used in the form of facings, inserts or buttons that are attached to electrode shanks or bodies made of a less-expensive material.

Electrode design is developed to work with workpiece and joint design in eliminating the need for holding and locating fixtures or clamps wherever possible, and in permitting rapid and easy loading and unloading of workpieces, filler metal and flux.

Provision for water cooling of electrode holders and electrodes is generally the same as in resistance welding (see the article on Resistance Spot Welding, beginning on page 401).

Arrangement of Electrodes

In most resistance brazing, the electrodes apply the brazing force and are arranged in line with the workpieces between them.

This arrangement of electrodes, workpieces and filler metal is shown in the figure at the top of this page. Part (a) of the figure shows a typical arrangement for resistance brazing small flat parts (or small flat portions of larger components) between opposed water-cooled metal electrodes of the conventional resistance welding type.

Part (b) of the figure represents a generally similar arrangement for resistance brazing large flat parts, usually of a highly conductive metal such as copper, between opposed carbon block electrodes attached to water-cooled copper alloy electrode holders.

In making some butt joints, or where space limitations or work configurations do not permit the use of opposed electrodes, the electrodes are merely connected on either side of the joint to provide the brazing current, and other means are used to apply the brazing force to the joint.

Press-fitted internal or external members can be resistance brazed to tubes or other workpieces of cylindrical shape without the application of force. Electrodes are attached to the ends of the tube, and the brazing current is passed not through the joint, but only through the tube. A filler-metal ring is preplaced at the joint, and the internal or external members to be attached are fluxed before they are press fitted. This technique has been used to a limited extent in resistance brazing of internal stainless steel baffle plates and external steel or copper fins to 1020 steel tubes in heat exchangers, as shown in part (c) of the above figure.

Filler Metals

Of the large number of filler metals available, only a few are used extensively in resistance brazing. Selection of filler metal for resistance brazing is similar to that for other brazing processes, as discussed in detail in the articles on those processes, and in the articles on the brazing of cast irons, stainless steels, aluminum alloys and copper alloys.

More attention is given in resistance brazing than in other brazing processes to selecting from the metallurgically compatible filler metals the one having the lowest brazing temperature, because in resistance brazing it is necessary to keep the maximum local temperature reached by the work as low as possible, while providing uniform heating of the abutting joint surfaces and the filler metal. Fluidity of the filler metal is not critical in most resistance brazing, because the filler metal is usually preplaced and the bond area is relatively large.

The general types of filler metal usually selected for resistance brazing various classes of work metals are:

Work metal	Filler metal
Steel, stainless steel, heat-resisting alloys, copper, copper alloys, nickel alloys	Silver alloys (BAg type)
Aluminum alloys	Al-Si alloys
Copper and copper alloys	Cu-P alloys

These types of filler metal all have relatively low brazing temperatures.

Silver Alloys (BAg Type). Of this group of filler metals, the two most commonly used are BAg-1 and BAg-1a (see Table 1 on page 686 in the article on Brazing of Copper Alloys). BAg-1 and BAg-1a are free-flowing alloys that permit the use of low brazing temperatures. In addition, their narrow melting ranges (20 F and 15 F, respectively) prevent liquation, making them insensitive to variations in the rate of heating or cooling. Their narrow melting ranges are also advantageous in step brazing (see page 648).

For making corrosion-resistant brazed joints in stainless steel, BAg-3 and BAg-18 are preferred.

In the examples in this article, BAg-1 was used in resistance brazing steel parts in Example 601 and leaded brasses in Example 602, while BAg-1a was used in resistance brazing solidified ends of braided copper conductor cable to copper in Example 605 and to chromium copper in Example 606.

Aluminum-silicon alloys (BAlSi type) used in resistance brazing of aluminum alloys are listed in Table 1 on page 675 in the article on Brazing of Alu-

minum Alloys. These low-melting alloys are available in sheet or wire form; BAlSi-2 and BAlSi-5 are also available as cladding on aluminum brazing sheet. Temperature must be controlled with special care in brazing of the lower-melting brazeable aluminum alloys, such as wrought alloy 6151 and cast alloys 43 and 356, for which the melting range of the filler metals approach closely or overlap the melting range of the work metal.

Copper-phosphorus alloys (BCuP type) are widely used as filler metals for resistance brazing of copper and copper alloys. They are low-cost, general-purpose filler metals and have the special advantage of being self-fluxing on copper (although flux is ordinarily needed when using them on copper alloys, as phosphorus does not reduce metallic oxides other than those of copper). BCuP-5 is by far the most widely used of the group. In some applications on copper or copper alloys, the wider melting range, higher working temperature, and lower ductility of the BCuP filler metals make them less suitable than the BAg types.

BCuP-5 filler metal was used in ten examples of resistance brazing of copper in this article and in the article on Brazing of Copper. BCuP-2 and BCuP-5 were used in turn in making two resistance step brazed joints in sequence in Example 599.

For higher ductility and corrosion resistance, silver brazing alloys sometimes are preferred to the BCuP filler metals for brazing of copper, in spite of the resulting need for fluxing, as in Examples 605 and 606. Difficulty in restricting flow of BCuP filler metals to joint surfaces may be a disadvantage.

Filler Metals for Step Brazing. When two or more joints are to be resistance brazed in sequence at points not widely separated on the same assembly, filler metals that differ in working temperature are selected, and the higher-melting filler metal is used first. Some overlap of the brazing temperature ranges can be tolerated, depending on the work metal, the size of the parts, proximity of the joints, the presence or absence of heat sinks, and the closeness of control of temperature.

Three general-purpose filler metals were used for all resistance brazing in one plant, in which the work metals were copper, copper alloys, carbon steel and electrical contact materials. The filler metals and their important characteristics were:

	Solidus temp, F	Liquidus temp, F	Brazing-temperature range, F
BCuP-2	1310	1460	1350 to 1550
BCuP-5	1190	1475	1300 to 1500
BAg-1a	1160	1175	1175 to 1400

Step brazing of copper and copper alloys was done on a variety of assemblies using these filler metals in sequence in any combination of two, as needed, brazing first with the filler-metal composition with the higher brazing-temperature range. In the example that follows, the two copper-phosphorus filler metals (BCuP-2 and BCuP-5) were used in resistance step brazing a simple but fairly massive assembly of four parts, for which the areas of the three joints were 12, 4½ and 4½ sq in.

(c) Current was turned off when filler metal was seen to melt. (d) Electrodes were released and work was removed when filler metal was seen to solidify.

Operation 1. Braze small block to large block (section A-A above).
Operation 2. Mill three slots ¼ in. wide by ¾ in. deep across full width of subassembly.
Operation 3. Braze two end plates to subassembly simultaneously (section B-B above).

Fig. 3. Circuit-breaker subassembly that was made from four parts by machining and resistance step brazing, using filler metals of different brazing temperature ranges, with reduced machining time and less waste of work metal than with original method of making the assemblies from three parts by machining and torch brazing (Example 599)

Example 599. Use of Resistance Step Brazing, With Filler Metals of Different Brazing Temperature Ranges, To Reduce Machining Time and Waste of Work Metal (Fig. 3)

The lower terminal for a 1200-amp circuit breaker (see Fig. 3) was originally made by machining the main portion of the terminal from a 1½-in.-thick solid bar of copper and then attaching the end plates by torch brazing. Nearly half of the copper was removed by milling when this method of manufacture was used.

In an improved method, the terminal was made from the four pieces of copper shown in Fig. 3 by resistance brazing and machining in three operations, as follows:

1. Braze small (3-by-4-in.) block to large block (section A-A in Fig. 3).
2. Mill three slots ¼ in. wide by ¾ in. deep across the full width of the subassembly.
3. Braze two end plates to subassembly simultaneously (section B-B in Fig. 3), using a lower-temperature brazing filler metal than in Step 1.

Changing to the improved method reduced the amount of copper machined away to about ⅛ of the amount originally removed, and substantially lowered material and labor cost. It was less expensive to braze the 3-by-4-in. block to the larger block and then to mill slots than it was to locate and braze four small pieces to the large block to form the slots.

A press-type, air-operated resistance welding machine fitted with hard carbon-graphite block electrodes clamped to large rectangular water-cooled class 2 (chromium copper) electrode holders was used. For each brazing step, the contact areas of the workpieces were brush coated with a paste of type 3A flux that had been further diluted with water, sheets of 0.003-in.-thick filler-metal foil were put in place, and the assembled parts were placed between the carbon electrodes. The flux was used to prevent oxidation of the work surfaces during the heating, although BCuP-2 and BCuP-5 are usually considered self-fluxing in brazing copper.

Filler metal for Step 1 was BCuP-2, which flows freely at 1350 F (flow temperature) and which was used at a working temperature of 1500 F; filler metal for Step 3 was BCuP-5, which flows freely at 1300 F and which was used at 1325 F.

The operator turned off the heating current when filler-metal flow was observed, and released the electrode pressure and removed the work when the filler metal was seen to solidify. Additional equipment details and brazing conditions are given in the table with Fig. 3.

A total of about 30 lower-terminal assemblies were resistance brazed in this way as replacement units for circuit breakers that had failed in service.

Form and Application of Filler Metal. Filler metal for resistance brazing is usually preplaced in the joint in the form of foil, wire, ribbon or a washer about 0.003 to 0.005 in. thick and of a shape and size to cover the approximate contact area of the joint. Filler metals not available in these forms can be preplaced in the joint in the desired amount as a powder, paste or preform that may also contain flux. High-speed injection can be used in mechanized operations, taking precautions to prevent separation and settling and to ensure the addition of a sufficient quantity of the filler-metal paste.

One technique for preplacing powdered filler metal is to dip the prefluxed parts into the powder, using flux of a viscosity selected to pick up the desired thickness of filler-metal powder. In some resistance brazing applications, one or both workpieces may be plated, clad or coated with a metal or alloy that serves as a filler metal.

The silver brazing alloys (BAg type) and the copper-phosphorus alloys (BCuP type), as described in the preceding sections, are commercially available as sheet, wire, powder or custom-made preforms. The aluminum-silicon brazing alloys (BAlSi type) are available as sheet or wire or as cladding on aluminum brazing sheet.

Preplacing the filler metal in the joint permits close control of the amount of filler metal used, thus avoiding waste, and also helps to obtain uniform filling of a maximum percentage of the joint area. The visible flowing of the preplaced filler metal is also helpful in establishing heating time, or in controlling heating time when manual timing is used.

Instead of preplacing the filler metal in the joint, filler metal can be applied after the joint has been heated to brazing temperature. The filler metal in the form of ribbon, wire or rod is fed to the joint, being drawn into the interface by capillary action. This method is used only rarely in resistance brazing.

The use of special forms of filler metal for resistance brazing is described in four examples in this article and in the article on Brazing of Copper Alloys. In Example 603, one of the workpieces was a copper terminal clad with a 0.003-in.-thick layer of BCuP-5. In Examples 605 and 606, the end of a braided copper conductor cable was "solidified" by dip tinning in BAg-1a and then coined to the desired shape and size, thus providing the filler metal for resistance brazing the end of the cable to a copper or chromium copper terminal. In Example 660, silver plating over an undercoating of plated copper on a high-carbon steel workpiece served as the filler metal for attaching a stranded copper wire by resistance eutectic brazing.

Fluxes and Cleaning

A flux is used in nearly all resistance brazing. It serves the same purposes in resistance brazing as in other brazing processes: providing a coating to prevent or minimize oxidation of the work metal during heating; dissolving oxides that are present or that may form during heating; and assisting the molten filler metal in wetting the work metal to promote capillary flow. However, the flux in resistance brazing has the additional function of serving as an electrical conductor to permit passage of the brazing current through the joint; most dry fluxes are nonconductors and must be mixed with water in order to conduct current.

Application. The flux is usually applied as a dilute water-base paste shortly before the parts and filler metal are assembled for brazing. Arcing and an explosion may occur if the paste is not a thin, uniform layer and free from lumps. If the flux should dry out before brazing is started, it may be possible to restore electrical conductivity by moistening it, but results are not always consistent. Once melted, the flux remains conductive.

If the filler metal is in powder form, flux can be combined with it in a fine-particle-size paste.

Selection. The same fluxes are used for resistance brazing as for other brazing processes on the same work metal, and their selection and properties are described in detail in the article on Torch Brazing and in the articles that describe the brazing of specific types of alloys.

Type 3A fluxes are general-purpose fluxes suitable for most metals that are commonly resistance brazed (although type 4 flux is needed for copper alloys that contain tin, aluminum or silicon); type 1 fluxes are used on aluminum alloy work metals.

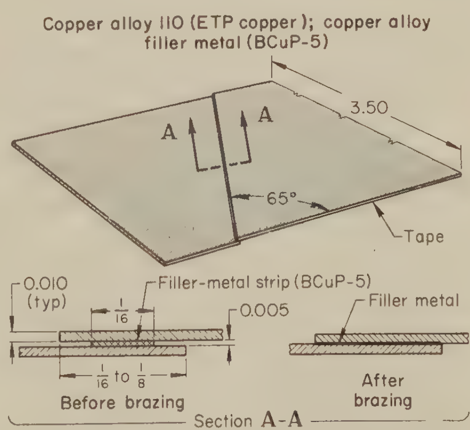
Brazing Without Flux. The two general situations in which a flux is not used in resistance brazing are brazing in a vacuum or a protective reducing-gas atmosphere (see the article on Furnace Brazing), and brazing of copper with a BCuP filler metal.

A flux is not ordinarily needed in resistance brazing of copper when a BCuP filler metal is used, because these filler metals are self-fluxing on copper by virtue of their phosphorus content. However, flux was used in step brazing of copper with BCuP-2 and BCuP-5 filler metals in Example 599.

In some special situations, brazing can be done in air without the use of flux, when brazing is done immediately after cleaning or mechanically abrading the joint surfaces. Special cleanliness of the workpieces made it possible to avoid the use of flux in the automatic resistance brazing of leaded copper alloy parts in Example 602, in which the filler metal was BAg-1.

Cleaning. As in other brazing methods, unless the work metal in the vicinity of the joint is free from grease, oil, dirt and interfering oxide coatings, chemical or mechanical cleaning must be done before resistance brazing, to permit wetting by the molten filler metal and capillary flow.

Removal of flux residues after resistance brazing is ordinarily necessary (as in other brazing processes), and is done by washing in hot water or, if this is not effective, by chemical or mechanical means. Removal of flux residues from braided cable and other parts where crevices are present is especially difficult and not always completely effective.



Machine	Press-type, air-operated, 30-kva resistance welding machine

Heating time	Approx 7½ to 9½ sec
Hold time	12 sec
Timing method	Fixed time (see text)
Joint strength	25,000 psi, min
Joint elongation	10% min

The brazed tape was continuously formed into a 1-in.-diam outer conductor tube for broad-band-transmission ocean cable in lengths of 20 nautical miles (see Example 604 and Fig. 8).

Fig. 4. Lap-joint design using 6-to-12t overlap and 65°-angle sheared ends in resistance brazing 0.010-in.-thick copper tape for subsequent forming into a tube (Example 600)

Joint Design

Joints for resistance brazing are usually lap joints, although other joint arrangements are used where lap joints are not suitable. Workpieces can have a wide variety of configurations, but the joint design must permit contact surfaces, usually flat or conforming, to be pressed together, ordinarily between electrodes, to make the joint.

Special-shape workpieces that are joined by resistance brazing include crossed wires, wires or tubes laid flat against the surface of a second part, stranded or braided wires or cables, shaft ends or collars butt-joined to flanges or rings, armature leads of various shapes inserted into slots in commutator bars, overlapping-spot-brazed flat stock, attachments to the interior of cylindrical shapes or in other types of recesses, and solidified joints of stranded or braided conductor cable to terminals. The wide variety of joint designs for resistance brazing is illustrated in the 16 examples in this article and the article on Brazing of Copper Alloys.

Contact areas of joints for resistance brazing can range from very small to moderately large. A procedure for resistance brazing copper wires only 0.002 to 0.005 in. in diameter to flat terminals is described in Example 603, and resistance lap brazing of ¾-in.-thick copper bars with a contact area of 3 by 4 in. is described in Example 599. Ordinarily, except in multiple-spot brazing (see Example 659), joint contact area is not much larger than that described in Example 599, and joint length is not much greater than joint width on larger parts, because it is difficult to obtain uniform current distribution (and thus, uniform heating) on such large or elongated joint areas. In addition, the capacity of the power source sometimes limits the size of the joint.

Lap joints are preferred to butt joints because they can be made with greater joint strength, as brazed joints are stronger in shear than in tension or bending. In lap joints, overlap should be at least three times the thickness of the thinner member for full joint strength, or at least 1½ times this thickness to avoid a significant loss in electrical conductivity across the joint. In the next example, overlap of 6 to 12 times stock thickness was used to produce strong joints of high conductivity.

Example 600. Design of Lap Joint To Provide Conductivity and Strength (Fig. 4)

Figure 4 shows the design for resistance brazed joints connecting copper tape, 3.5 in. wide by 0.010 in. thick, used for making the outer conductor for broad-band-transmis-

sion ocean cable in lengths of 20 nautical miles. Use of an overlap 6 to 12 times the work-metal thickness provided electrical conductivity across the joint equal to that of the work metal, and helped give joint strength that would withstand subsequent forming of the tape into a tube. The ends of coils of tape 3000 ft long to be joined by brazing were sheared at 65° to its length (instead of 90°) so that the lapped edges of the brazed joint would not be directly opposite each other when the tube was formed (see Fig. 8, page 653).

Flux residues could not be tolerated on the brazed connections, and the manufacturing procedure for the continuous cable did not permit cleaning after brazing. Consequently, BCuP-5, a filler metal that is self-fluxing on copper, was chosen for resistance brazing. Its comparatively low electrical conductivity (10% IACS) was compensated for by the width of the overlap and the low thickness of the layer of filler metal in the completed joint (typically 0.002 in.).

Brazing was done in a 30-kva press-type resistance welding machine fitted with 1-in.-thick rectangular electrographite electrode blocks having a working surface 4 in. long by ¼ in. wide.

The ends of the copper tape were sheared at an angle of 65° (see Fig. 4) and a 1/16-in.-wide strip of filler metal was placed between the overlapping surfaces at the joint. A heating time of 7½ to 9½ sec was used to produce joints having a strength of at least 25,000 psi and elongation of at least 10%. The brazing schedule was established on the basis of destructive testing of brazed joints made at different machine settings.

Where practical, joint design is coordinated with electrode design so as to make the workpieces self-aligning (or, ideally, self-nesting), and thus to minimize the need for special fixtures. Joint design must permit the workpieces to move when the filler metal melts and flows, and should at the same time maintain proper workpiece alignment until the filler metal has solidified completely.

The contacting surfaces of the workpieces must be designed to fit closely together during brazing so as to avoid local overheating, permit capillary action, and minimize voids in the brazed joint. Forming or machining of the areas to be joined is sometimes necessary for proper fit. The design also must permit the application of the electrode force without distortion of the workpieces.

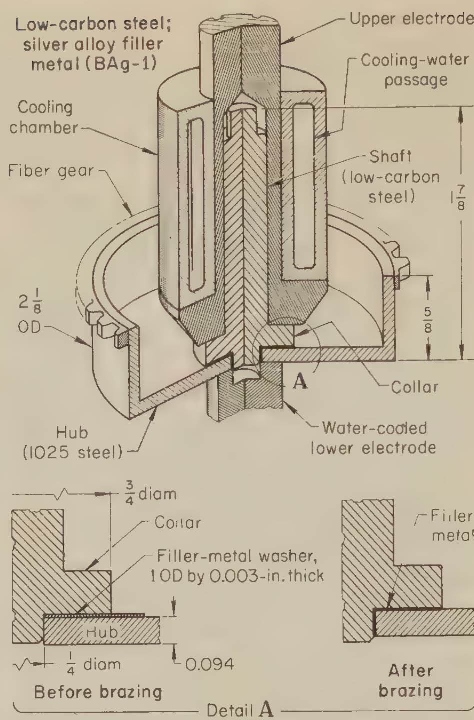
In addition, joint design, in conjunction with electrode design and arrangement, should permit easy assembly of workpieces and filler metal, convenient fluxing (if a flux is used), and easy loading and unloading of the machine.

A variety of joint designs are illustrated in the 16 examples of resistance brazing in this article and in the article on Brazing of Copper Alloys. The various aspects of joint design described in the preceding paragraphs are illustrated in the next example.

Example 601. Design of Workpieces and Electrodes for Self-Fixtured Resistance Brazing (Fig. 5)

In resistance brazing a 0.094-in.-thick 1025 steel hub to a 3/8-in.-diam low-carbon steel shaft in a press-type resistance welding machine, the workpieces and the electrodes were designed for self-fixturing, as shown in Fig. 5.

Resistance brazing was the only available method suitable for joining parts of the exact design shown in Fig. 5, because of the need to avoid heat damage to the fiber



Machine ....Press-type, air-operated, 50-kva resistance welding machine, rated at 80 strokes per hour

Timing method ....Electronic
Production rate ....80 assemblies per hour

Fig. 5. Shaft-and-hub assembly for which workpieces and electrodes were designed for self-fixtured resistance brazing. Heat input was controlled and localized to avoid damaging the fiber gear that was bonded to the periphery of the hub. (Example 601)

gear. If redesign of the shaft for annular projection welding had been permissible, that method would also have been suitable.

For joint strength, the shaft had a collar to provide a flat annular contact surface with an ID of ¼ in. and an OD of ¾ in. The ¼-in.-diam chamfered locating tip on the bottom of the shaft extended through the clearance hole (diametral clearance of 1/32 in.) in the hub and projected about 0.015 in. into a clearance recess (diametral clearance of 1/32 in.) in the lower electrode.

The flat upper surface of the collar on the shaft provided an annular contact surface for the upper electrode, and the upper portion of the shaft fit into a clearance hole (diametral clearance of 1/32 in.) in the upper electrode.

In preparing the assembly for brazing, the operator first applied a water-base paste of type 3A flux to the shaft by dipping, and then slipped a washer of BAg-1 filler metal and the hub over the locating lower tip of the shaft, fitting them against the lower surface of the collar. Then, holding the assembly in an upright position by the hub, the operator inserted the shaft into the recess in the upper electrode and lowered the upper electrode at a controlled rate until the electrodes were closed on the assembly at low pressure. Pushing the start switch on the welding machine actuated the brazing force and current, and the brazing sequence was completed automatically.

The press-type resistance welding machine was air operated and was rated at 50 kva and for operation at 80 strokes per hour. The specially designed upper electrode had a class 14 (molybdenum) facing on a class 2 (chromium copper) shaft; the lower electrode was class 2 (chromium copper). Both electrodes were water cooled.

If the flux dried out before the assembly could be brazed, dipping the assembly in water restored the conductivity of the flux so that the brazing current could be passed through the joint.

Advantages of resistance brazing in this application were (*a*) the convenience of providing localized and controlled heat input to avoid damaging the fiber gear bonded to the periphery of the hub (see Fig. 5); (*b*) the simplicity and ready availability of the equipment; and (*c*) the low level of required operator skill.

Production rate for resistance brazing this assembly was about 80 assemblies per hour. Additional details of equipment and operation are given with Fig. 5.

Resistance Brazing as a High-Production Process

Most resistance brazing is done with resistance welding equipment, which is readily adapted for mechanized production of intermediate or large quantities of resistance brazed assemblies. Example 603 describes fully mechanized (including loading and unloading) high-speed mass-production resistance brazing of copper wires to terminals in a ferrite-core storage frame used in a computer.

All operations except loading and unloading were done automatically in mass production in several other examples in this article and in the article on Brazing of Copper Alloys, including Examples 597, 602 and 660. Resistance brazing of intermediate quantities was done semiautomatically in Examples 598 and 600, and manually in Example 658.

In Example 658, a total of 100,000 resistance brazed connections were made annually, using a portable resistance welding machine and hand-held tongs. In Example 598, intermediate quantities of cross-wire connections were made semiautomatically, using a traveling bench-mounted portable welding head in a resistance brazing operation that was integrated with other assembly operations in a mechanized coil-winding machine. In Example 600, the ends of coils of copper strip or tape were semiautomatically joined by resistance brazing as part of the continuous fabrication of 20-nautical-mile lengths of ocean cable.

Special Techniques Used in Resistance Brazing

Characteristics common to nearly all resistance brazing operations include the following: (*a*) the use of filler metal, (*b*) localized heat input, (*c*) passage of the heating current through the joint, which is held together under pressure, and (*d*) use of standard or modified resistance welding machines.

In most other respects, as the examples show, resistance brazing applications vary widely. They range from the simplest manual operations on small quantities of noncritical parts to fully mechanized high-speed mass-production of brazed assemblies to rigid standards. Workpieces vary widely in size, shape, and type and condition of

material, and special techniques and procedures often are needed.

The application of a number of special techniques to resistance brazing is described in the following sections.

Step brazing involves making two or more brazed joints in succession on the same assembly, using filler metals that have progressively lower working-temperature ranges, and is conveniently done by resistance brazing, in which the heat input is localized and can be controlled accurately. Step brazing is used extensively in making circuit breakers and other types of electrical switchgear and power distribution equipment; Example 599 describes step brazing a circuit-breaker subassembly.

Use of Fast Follow-Up. The inertia of the moving mass of the electrode holder and electrode can prevent electrodes and workpieces from responding quickly enough to the melting of the filler metal, especially when small parts are being brazed. The delayed response and rebound of the electrode holder and the workpieces can then cause expulsion of too much of the filler metal, producing a weak brazed joint bonded over only a small percentage of its area.

Fast follow-up is especially important in resistance brazing with filler metals (such as BAg-1 and BAg-1a; see Table 1 on page 686 in the article on Brazing of Copper Alloys) that flow at a temperature only 15 to 20 degrees above the temperature at which they start to melt. For applications using such filler metals, resistance welding machines are equipped with special low-inertia, low-friction electrode holders that permit rapid follow-up by the electrode when the filler metal flows.

One type of low-inertia welding head is described in the article on Projection Welding and is illustrated in Fig. 5 on page 437 in that article. A specially designed spring-loaded decoupling system was used in a gravity-operated brazing head in Example 603 for resistance brazing copper wires to terminals. In the example that follows, a spring-loaded fast-follow-up electrode holder was used in an air-operated automatic resistance welding machine in brazing a post-and-flange assembly.

Example 602. Use of a Low-Inertia Upper-Electrode Holder for Fast Follow-Up in Automatic Resistance Brazing (Fig. 6)

The binding post and flange shown in Fig. 6 were resistance brazed with BAg-1 filler metal (solidus of 1125 F; liquidus of 1145 F), used as a preformed ring. Because of the short time interval between melting and flowing of this filler metal, a special low-inertia, low-friction upper-electrode holder was used to provide fast follow-up and to minimize rebound. The spring-controlled action of this electrode holder kept the two workpieces in intimate contact with the filler metal throughout the melting-and-flowing sequence, and resulted in the proper capillary action and maximum filling of the brazed joint.

Brazing was done on a 75-kva automatic resistance welding machine with a 440-v input, a 4-to-7.33-v output, and synchronous controls. A hollow lower electrode was shaped to hold the post. The filler-metal preform and the flange rested on the collar of the binding post (see Fig. 6). The upper electrode was ⅝ in. in diameter and was flat. Both electrodes were of RWMA class 2 material (chromium copper).

The procedure was as follows: The two parts were cleaned by acid dipping and were assembled with a preform of 0.032-in.-diam BAg-1 wire. The assembly, which was self-fixturing, was mounted by hand in the lower electrode. Force, voltage and time were controlled automatically. The assembly was clamped with a force of 190 lb and heated with a secondary voltage of 6.9 v for 27 cycles, or a little less than half a second.

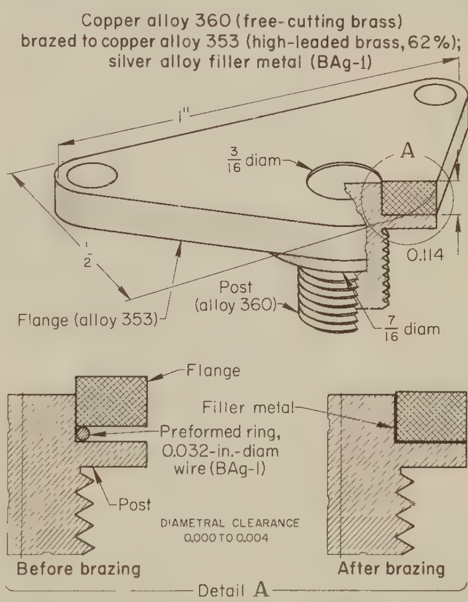
It was necessary for the flange to bottom on the shoulder of the binding post and be perpendicular to it within one degree. The filler metal was required to show on the lower side of the flange all the way around the joint. Production rate was 278 assemblies per hour. Production costs are given in the table that accompanies Fig. 6.

Electrode cost per assembly was negligible, and the job was done on a machine that had already been amortized. Equipment details and conditions for brazing also are given in the table with Fig. 6.

The post was made of copper alloy 360, and the flange, of copper alloy 353. Arc or resistance welding processes are not ordinarily suitable for joining leaded brasses of such high lead content (nominally 2% for alloy 353, and 3% for alloy 360), because the low-melting lead concentrates in the grain boundaries during exposure to welding temperatures, causing cracking and weakening of the joints. With the use of resistance brazing, and a small and closely controlled heat input, these difficulties were avoided.

The heat for brazing was generated chiefly in the filler metal and the regions of the workpieces in the immediate vicinity of the joint. Electrical conductivities of the materials involved were as follows, expressed in per cent IACS: RWMA class 2 electrodes, 75 minimum; BAg-1 filler metal, 28; copper alloy 360 (post), 26; and copper alloy 353 (flange), 26. The use of class 2 electrodes for this operation allowed localization of heating in the joint and use of a low total heat input.

Resistance brazing was preferred to torch brazing because of better controllability of heat input, greater speed and lower operator-skill requirements, and was preferred to induction brazing because of the higher cost of equipment for induction brazing and the availability of resistance welding equipment in the plant.



Machine	Press-type, air-operated, 75-kva automatic resistance welding machine, synchronous controls, equipped for fast follow-up (see text)
Loading and unloading	Manual
Filler metal	Preformed ring of 0.032-in.-diam BAg-1 wire
Flux	None
Precleaning	Acid dip both parts
Electrodes	RWMA class 2 (chromium copper), ⅝-in. diam(a)
Electrode force	190 lb
Brazing voltage	6.9 v
Heating time	27 cycles
Production rate	278 assemblies per hour

Production Cost per Assembly

Labor (1 operator at $3.36 per hour)	$0.0121
Filler metal (at 35¢ per 100 assemblies)	0.0035
Power (at 1.5¢ per kwhr)	0.000094(b)
Electrodes	Negligible
Machine	0.00(c)
Total	$0.0157

(a) Upper electrode had a flat face; lower electrode was recessed to hold post. (b) Based on consumption of 50 kwhr per brazed joint. (c) The machine had already been amortized.

Fig. 6. Post-and-flange assembly that was automatic resistance brazed with BAg-1 filler metal using a special low-inertia upper-electrode holder for fast follow-up (Example 602)

Brazing Plastic-Coated Wire. Organic coatings, grease, oil, oxides and other types of nonmetallic materials must ordinarily be removed from the contact surfaces of workpieces to be resistance brazed, to permit wetting of the entire joint area by the molten filler metal. Some types of organic coatings, however, can be removed readily and completely by electrode heat and pressure as part of the brazing sequence.

In the example that follows, a special energy-supply system and a dual electrical circuit were used (*a*) to remove polyurethane insulation from copper wire with the electrode, (*b*) to braze the stripped wire to a terminal, and (*c*) to burn off residues from the electrode after brazing each joint. The brazing electrode was made of a precious metal alloy to withstand this heating sequence and to resist alloying with copper or the BCuP-5 filler metal that was used. In addition, fast follow-up was provided by a specially designed spring-loaded decoupling system in a gravity-operated brazing head.

Example 603. Use of Capacitor-Discharge Energy Pulses To Remove Insulation and Resistance Braze (Fig. 7)

Resistance heating of the brazing electrode by a preliminary capacitor-discharge energy pulse was used to melt and strip insulation from the contact surfaces of polyurethane-coated copper wires in resistance brazing them to terminal pads in a ferrite-core storage unit for a computer (see Fig. 7). An energy pulse from a capacitor was also passed through the retracted electrode between brazing operations to burn residual insulation material from the electrode tip. The brazing electrode was made of 60Pt-40Rh to withstand a temperature of 1700 F in continuous high-speed production and to resist alloying with copper or filler metal. Fig. 7 (view at upper left) shows the general construction of a single "two-dimensional" ferrite-core memory frame, and detail A is an enlarged view of a portion of the frame.

The copper conductor of the wires was 0.005 in. in diameter (other conductor sizes, down to 0.002 in. in diameter, were used in other frames of this type), and the over-all diameter for the wire shown, including the insulation, was about 0.007 in. The terminals were punched from 0.004-in.-thick copper strip clad on both sides with a 0.003-in.-thick layer of BCuP-5 brazing filler metal. (Section C-C, bottom left, Fig. 7, shows a conductor wire and terminal.)

The terminals were encased in the thermoplastic frame, with their outer contact fingers extending from the sides of the frame, and the terminal pads embedded

Fig. 7. Ferrite-core memory frame for a computer, in which 392 connections were made by capacitor-discharge resistance brazing, in the setup shown. Pulsed energy from capacitors was used to melt the polyurethane insulation from the wire during brazing and to burn residues off the 60Pt-40Rh electrode tip between brazing operations. (Example 603)

flush with the surface of the frame. Locally stripped contact surfaces of the wires were brazed to the terminal pads, and the scrap ends of the wires were then broken away, leaving the brazed assembly shown in the over-all and detail views in Fig. 7.

Circuit. The brazing setup and the circuit are shown schematically at the upper right in Fig. 7. The gravity-loaded resistance brazing tip was a loop of 0.020-in.-diam 60Pt-40Rh wire with a 0.010-in.-wide flat (section D-D, Fig. 7) honed on the bottom to provide the contact surface. The tip was percussion welded to the 0.040-in.-diam copper electrode shanks, as described in Example 177 in the article on Percussion Welding. The spring-loaded return electrode, which had two tips that contacted the terminal pad on each side of the wire and 0.010 to 0.030 in. behind the brazing tip, was made of beryllium copper. The small controlled amounts of resistive heat needed for brazing were supplied by the discharge of capacitors that were automatically recharged by rectifiers (not shown in Fig. 7) immediately before each energy pulse.

Brazing Procedure. The wire leads, held by scrap ends extending 4 to 6 in. beyond the edges of the frame, were laid across the terminal pads, and the brazing electrode was pressed down on each of them in turn. To melt the polyurethane insulation, the switch was closed in the circuit identified in Fig. 7, top center, as circuit No. 1. This passed a current through the loop-shape brazing electrode, producing enough heat to break down and strip the insulation (section C-C, bottom center). Electrical contact was thus firmly established between the brazing electrode and the wire lead and between the lead and the terminal. To initiate brazing, the switch in circuit No. 2 was closed, causing a pulse of current to flow from the electrode through the wire and terminal and back through the return electrode. This pulse generated enough heat at the wire-terminal interface to melt the filler metal at the contact area to a depth of about 0.0005 in. and produce a fillet on each side of the wire (Fig. 7, section C-C, bottom right).

The brazing electrode was cleaned before each braze by pulsing current through the tip (circuit No. 1 in Fig. 7) to vaporize polyurethane residues. Timing of the entire sequence of operations was done with a solid-state timing device.

Additional equipment details and brazing conditions are given in the table with Fig. 7.

Design for Fast Follow-Up. The sudden melting of the filler metal was too rapid for a conventionally mounted welding head to follow. The electrode mass was made as low as possible and the electrode was decoupled from the applied weight by a spring so that it could follow rapidly the collapse of the filler metal, thus avoiding rebound, expulsion of molten filler metal, and destructive arcing.

Testing of Joints. The removal of the scrap ends of the wires, which was done manually, provided a test of the joint strength. On properly brazed joints, the strength of the joint was greater than the tensile strength of the wires, and the scrap end broke away, leaving the joint intact (Fig. 7, upper right and section B-B).

The operator usually peeled away the scrap ends in clusters, pulling in a direction away from the free end of the wire.

Process reliability was about 99.7%. Over a period of several years of mass-production use of this joining procedure, none of the brazed joints failed in service.

Alternative Methods. Previously, these assemblies had been joined by wrapping the wire around terminals designed for the purpose and dip soldering the assembly in molten tin-lead solder. The molten metal

removed the plastic insulation and fused the joints. However, heat from the molten bath often damaged the assembly, the process was difficult to automate, dip soldering did not lend itself to high-density packing, the assembly had to be fluxed, and subsequent cleaning was difficult.

Preventing Overheating. One technique used in resistance brazing to prevent overheating of the workpiece is the use of pulsed current. In Example 656 in the article on Brazing of Copper Alloys, six pulses of 11 cycles heat time and eight cycles cool time were used to heat the joint to brazing temperature in attaching copper leads to a copper commutator bar without significant annealing of the commutator bar.

A single energy pulse from a capacitor was used in Example 603 in this article to provide the small, closely controlled, rapid heat input needed to resistance braze copper wires 0.002 to 0.005 in. in diameter to flat terminals.

In Example 598, the cross-wire joint and precision timing and current control were the major factors in limiting the heat input to the work; and in Example 602, joint design and the relative electrical conductivities of the electrodes, work and filler metals made possible highly localized heating and the use of low total heat input.

In Example 659 in the article on Brazing of Copper Alloys, successive overlapping spot brazing was used to prevent overheating in resistance brazing copper strip to copper bus bar with a total joint area 4 in. wide by 8 in. long. In the example that follows, small overlapping spot brazes were also used to avoid annealing of adjacent high-carbon steel wires in resistance brazing of repair patches to the copper inner conductor tube of ocean cable.

Example 604. Use of Overlapping Spot Resistance Brazing To Attach Repair Patches to Copper Tube (Fig. 8)

Weld defects or unwelded sections ("weld skips") in the seam welded inner conductor tubes of broad-band-transmission ocean cable were repaired by resistance brazing patches over the defects or unwelded sections, as shown in Fig. 8.

Cable Manufacture. The ocean cable was made in a process that was operated continuously for over 80 hr to produce a section of cable 20 nautical miles long. The core, which was the strength member of the cable, consisted of 41 high-carbon steel wires of five different sizes stranded in a tubular strander, in a pattern designed for maximum strength, and dimensioned in a closing die to a 0.290-in. outside diameter.

The inner conductor was formed around the steel core into a 0.5-in.-diam tube from 0.023-in.-thick copper alloy 102 (OF copper) strip, and was then gas tungsten-arc seam welded, reduced in diameter in a series of reducing rolls to fit tightly around the steel wire, and drawn through a final die to dimension it and to force some of the copper into the interstices of the stranded steel core.

Subsequent steps in the manufacture of the cable were: continuous extrusion of low-density polyethylene around the inner conductor, forming of the copper outer conductor into a tube around the polyethylene dielectric layer (see Example 600 for resistance brazing of copper strip to make the outer conductor), and extrusion of the outer sheath of black ethylene plastic.

Defects in Inner Conductor. Pinholes, weak spots and "weld skips" in the seam of the inner conductor generally originated with defects or irregularities in the copper strip. The seam was visually inspected for flaws and continuously checked for weld skips by a "seam integrity tester" after welding, and was tested again in the same way after final sizing of the inner conductor. The tester consisted of a bridge circuit in which two coils surrounded the inner conductor and formed two legs of the bridge. When a weld skip passed through the first coil, the bridge became unbalanced, triggering an alarm. A skip 1⁄32 in. or more in length could be detected.

It was important to detect weaknesses or weld skips before proceeding to subsequent operations. The extrusion process built up considerable pressure in trapped air inside the welded inner conductor because of the heat generated and the choking effect of the 20-nautical-mile length. Where there were flaws or skips in the welding of the inner conductor, this compressed air blew bubbles in the extruded polyethylene, creating voids in the dielectric and impairing the electrical function of the cable. Defects that were not detected and repaired before extrusion of the inner dielectric could necessitate repair or removal of the defective section of cable later in the manufacturing process, with greater difficulty and cost.

Only four repairs of any kind were permitted in a 20-nautical-mile length of cable. The average number of inner-conductor repairs per cable length was 2.3. Reliability of these resistance brazed patch repairs was 98%. The repaired seam had to be capable of withstanding more than 80 psi air pressure after the inner conductor had been subjected to 50 reverse bends over a 3-ft radius.

Repair Technique. Finding a technique for repairing defects in the inner-conductor seam was complicated by the need for a ductile patch and by the fact that excessive heat might anneal the steel core wires and thus weaken the cable unacceptably.

Techniques that were tried and found unsatisfactory used tin-lead solder patches, epoxy patches and resistance welded gold-plated copper patches; the last method overheated the steel core wires.

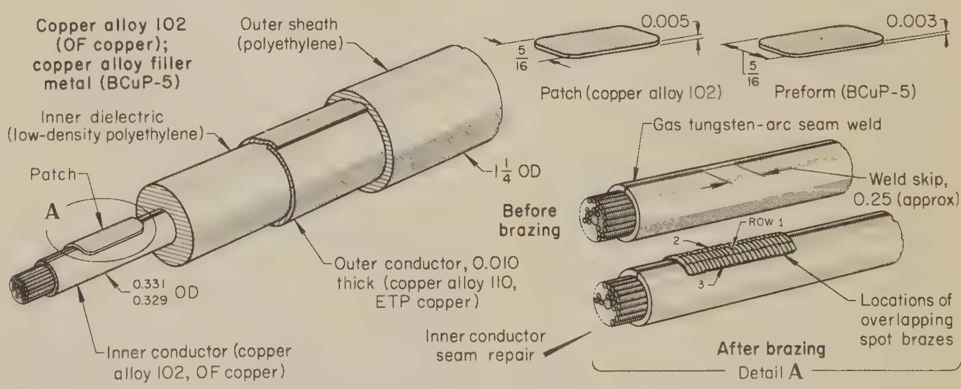
The technique that was finally adopted consisted of resistance brazing 0.005-in.-thick copper alloy 102 patches over the defects, using 0.003-in.-thick strips of BCuP-5 filler metal and a resistance welding machine. A strip of filler metal and a copper patch, each 5⁄16 in. wide and of a suitable length, were placed over each defect (see Fig. 8). Then the patch was stitched all over with overlapping spot brazes, making one braze at a time. The individual spot brazes were about 1⁄8 by 3⁄16 in., and were spaced on 0.030 to 0.040-in. centers, as shown in Fig. 8. Afterward, the patch was smoothed with emery paper to keep the diameter of the inner conductor from exceeding 0.333 in., and was polished with crocus cloth.

The electrode tips were machined to conform to the curvature of the inner conductor. Both electrodes were made of 5⁄8-in.-diam class 1 material (cadmium copper) faced with class 12 material (copper-tungsten). The upper electrode had a groove with a 0.167-in. radius and the face was reduced to 1⁄8 in. wide. The lower electrode also had a groove with a 0.167-in. radius, but the face was not reduced in width, and thus provided maximum support for the conductor and a large contact area.

Brazing force was 100 lb, and the current and heating time were selected to provide just enough heat to melt the brazing filler metal completely. Additional equipment details and brazing conditions are given in the table that accompanies Fig. 8.

Solidified Joints. Resistance brazing is frequently used to join braided or stranded electrical conductors, especially in the larger sizes (rated to carry currents of about 60 amp or more), to each other or to other types of conductors. Braided conductors of smaller sizes are conveniently joined by resistance welding, thus avoiding the use of filler metal and flux, as in Example 420 in the article on Resistance Welding of Copper Alloys. However, the currents needed for resistance welding of heavy braided or stranded conductors are prohibitively high, and conductor cables rated for 60 amp or more are more conveniently joined by resistance brazing of solidified joints.

This type of joint has better resistance to corrosion than mechanically crimped connectors and has the additional advantage that it can be machined and formed much like a single continuous piece of metal. As shown in



Machine .... Portable resistance welding machine, 50 kva	Electrode force .... 100 lb

	Joint reliability 98%

(a) Mounted in fixed ways; upper-electrode holder, cantilever mounted; lower-electrode holder, stationary. (b) Class 1 (cadmium copper), 5⁄8-in. diam, with class 12 (copper-tungsten) conforming tips.

In making the repair, overlapping spot brazes about 1⁄8 in. wide by 3⁄16 in. long and spaced on 0.030 to 0.040-in. centers were made one-at-a-time in three rows, as shown in Detail A, between opposing electrodes, the tips of which conformed to the curvature of the workpiece. The lower electrode had a much larger contact area than the upper electrode, so that it functioned only as a return electrode.

Fig. 8. Ocean cable that was made in continuous production in lengths of 20 nautical miles, and copper alloy patch that was overlapping-spot resistance brazed to the copper alloy inner conductor tube to repair gas tungsten-arc seam welding defects in the tube (Example 604)

Heating time	5 sec
Hold time	20 cycles
Post treatment	Water quenching(b)
Production rate	250 assemblies per hour

(a) Filler metal was applied to the end of the braided cable by dip tinning to produce a solidified end. (b) Assemblies were dropped into cold running water immediately after brazing.

Fig. 9. Solidified end of a 60-amp braided DLP copper conductor cable and ETP copper terminal that were resistance brazed using molybdenum-face copper alloy electrodes to permit short heating time (Example 605)

Examples 605 and 606, the solidified end of the braided or stranded cable provides the filler metal for resistance brazing. Where the shapes of the cable and the other workpiece permit, solidification and brazing can be done simultaneously to minimize exposure to heating.

In the two examples that follow, the ends of braided conductor cables were joined to other types of workpieces by resistance brazing. The end of the braided cable first was resistance welded using class 14 (molybdenum) electrodes to fuse the strands partially and to consolidate the braid. It was then dip tinned with BAg-1a brazing filler metal, coined to the desired shape and size, and finally resistance brazed to a solid terminal or other workpiece.

Example 605. Use of Molybdenum-Faced Electrodes To Permit Short Heating Time in Brazing a Solidified Joint (Fig. 9)

In resistance brazing the solidified end of a 60-amp braided copper conductor cable to a copper terminal, the heating time had to be minimized to avoid excessive annealing of the terminal and excessive penetration of filler metal into the braided cable.

By using water-cooled class 2 (chromium copper) electrodes with a class 14 (molybdenum) facing, the joint was made with a heating time of 5 sec. The braided cable, with its resistance welded, dip tinned and coined solidified end, and the terminal are shown at the left in Fig. 9. The completed assembly, ready for unloading, is shown between the electrodes at the right in Fig. 9.

A bench-mounted resistance welding machine was used. Timing of the brazing sequence was automatic. The production rate for brazing was 250 assemblies per hour. Equipment details and brazing conditions are given in the table with Fig. 9.

Carbon electrodes, simpler to prepare and less expensive than high-resistivity metallic electrodes, often are used in short-run resistance brazing applications, where their low resistance to wear is not important. If heat input to the joint is not critical, manual timing also can be used, as in this example:

Example 606. Use of Carbon Electrodes and Manual Timing in Short-Run Brazing of a Solidified Joint (Fig. 10)

Carbon electrodes, which are simpler to prepare and less expensive than molybdenum-faced copper alloy electrodes, were used for joining small quantities of alloy 184 (chromium copper) bolt heads to flat braided 100-amp copper alloy 120 conductor cable, as shown in Fig. 10. Heat input to the joint was less critical in this application than in the one described in Example 605, and manual timing was used.

A specially designed bench-mounted manual press-type resistance welding machine rated at 50 kva was used. Application of the brazing current was manually controlled by the operator by means of a foot switch that operated a magnetic contactor. The operator observed the joint while the current was applied and released the switch to shut off the current when the filler metal was seen to flow. Force was applied by deadweights on the ram. The electrodes, normally closed, were opened by foot pedal to insert or remove assemblies.

The carbon electrodes used were a medium-hard grade of carbon-graphite that had a resistivity of 0.0005 ohm-in.

In preparation for brazing, the bolt was degreased. The end of the braided cable was resistance welded using class 14 (molybdenum) electrodes to partially fuse the strands and consolidate the braid, and then was dip tinned with BAg-1a brazing filler metal and coined to shape and size.

The bolt and the solidified end of the cable were assembled between the carbon electrodes, as shown in Fig. 10, and were resistance brazed. The assembly was held clamped between the electrodes until the operator observed solidification of the filler metal. Then the electrodes were manually opened and the assembly was removed and dropped into cold running water.

By use of this procedure, brazed joints having good strength and electrical conductivity were produced simply, and at low cost and without excessive annealing or softening of the chromium copper bolt head. Additional equipment details and brazing conditions are given with Fig. 10.

Copper alloy 120 (DLP copper) brazed to copper alloy 184 (chromium copper); silver alloy filler metal (BAg-1a)

(a) Filler metal was applied to the end of the braided cable by dip tinning to produce a solidified end. (b) Carbon-graphite, medium hard, 1-in. diam; mounted in class 2 (chromium copper) water-cooled holders (not shown). (c) Applied by deadweights on ram. (d) Heating was terminated by operator when flow of filler metal was observed. (e) Load was released by operator when solidification was observed. (f) The completed assemblies were dropped into cold running water immediately after brazing.

Fig. 10. Solidified end of flat braided DLP copper conductor cable and chromium-copper bolt head that were joined by resistance brazing using carbon electrodes and manual timing (Example 606)

Alloy (Eutectic) Brazing. Because resistance brazing in a resistance welding machine offers localized, controlled heat input to the joint and controlled application of brazing force, it is well suited for alloy, or eutectic, brazing.

Example 660 in the article on Brazing of Copper Alloys describes resistance eutectic brazing of copper wire to high-carbon steel that previously had been plated with an undercoat of copper and then with silver.

Resistance brazing with carbon electrodes has been used to join EC aluminum workpieces with copper-foil filler metal 0.001 to 0.005 in. thick. The pressure on the contact area of the workpieces was maintained at 1200 to 2000 psi. Current densities of 2500 to 4000 amp per square inch and heating times of 3 to 60 sec (depending on the foil thickness and joint area) were used for complete fusion of the copper. No flux was used, and the workpieces were precleaned by vapor degreasing.

All of the copper filler metal alloyed with the aluminum work metal to form a molten phase, most of which was squeezed out of the joint. The brazed joints, including butt joints, had electrical conductivity essentially the same as that of the work metal. [For additional information and references on this technique, see Kent R. Van Horn, Ed., "Aluminum", Vol. III, p 510-511 (ASM, 1967), and James R. Terrill, *Welding Journal,* Sept 1962, p 799-804.]

Dip Brazing of Steel in Molten Salt

*By the ASM Committee on Brazing of Steel**

DIP BRAZING in molten salt, also called salt bath brazing and molten chemical-bath dip brazing, is a process in which the assembly to be brazed is immersed in a bath of molten salt, which provides the heat and may provide the fluxing action for brazing. The bath temperature is maintained above the liquidus of the filler metal but below the melting range of the base metal. This article describes the application of dip brazing to carbon and low-alloy steels with silver alloy, copper-zinc alloy, and copper filler metals. For information on dip brazing of cast iron, stainless steel, aluminum alloys and copper alloys, see the articles on pages 660 to 702 in this volume.

Advantages of salt bath brazing include the following:

1. Time for heating is about one-fourth that required in a controlled-atmosphere furnace.
2. A protruding joint can be selectively brazed by partially immersing the assembly.
3. A cocoon of frozen salt forms instantly around the cold assembly when it is immersed in the molten salt, and this usually prevents premature melting of the brazing filler metal by providing a temporary insulator.
4. By selection of an appropriate salt composition, it is often possible to combine heating and fluxing of the work in a single step, although flux can be applied to the joint and dried before brazing.
5. Brazing can usually be combined with carburizing or hardening, without the necessity for a separate reheating operation.
6. More than one assembly can be brazed at the same time, production being limited only by the size and heating capacity of the furnace. Also, several joints in an assembly can be brazed at the same time.
7. The workpiece is protected from scaling or decarburization by a thin film of salt that adheres to the surface of the assembly when it is removed from the salt bath.
8. Removal of the salt film is accomplished by dissolving during quenching or washing operations. When flux is used, there is no removal problem; flux is either dissipated during the brazing operation or dissolved simultaneously with the salt film during washing.
9. The density of the molten salt supports a considerable portion of the weight of the workpiece so that, in effect, the assembly weighs less when immersed, which can reduce the likelihood of distortion during heating.

Limitations of salt bath brazing include the following:

1. The process is not generally used for intermittent operation, being better suited for work that requires daily production.
2. Joints that do not protrude from the assembly cannot be selectively brazed by partial immersion; most or all of the assembly must be heated to the brazing temperature in order to braze such joints.
3. The workpieces must be dry and free of all moisture, because the molten salt reacts violently with moisture and will spatter and may even explode. It is necessary to preheat all work if moisture is present.
4. Buoyant parts are difficult to braze in a salt bath because they cannot be easily submerged.
5. The shape of the part must be such that it will not trap air or salt and will drain completely after removal from the salt bath.
6. The assemblies should not require large, complicated fixtures.

Furnaces

A salt bath furnace consists essentially of a metal or ceramic (refractory) pot that serves as a container for the molten salt. Some salt bath furnaces are externally heated by gas, oil, or electrical resistance; this type of furnace lends itself more readily to intermittent operation, and is not widely used for high-volume production. On the other hand, furnaces internally heated by immersed or submerged electrodes are not well suited to intermittent operation, but they are used for high-volume production. Descriptions of internally and externally heated salt bath furnaces, including illustrations, operating characteristics, advantages, disadvantages, and some of the precautions in use are given on pages 135 to 138 in the article "Liquid Carburizing", in Volume 2 of this Handbook. Figure 1 in the present article shows the typical construction of the four principal types of furnaces.

Externally heated furnaces are usually gas-fired or oil-fired and less frequently are heated by means of electrical resistance elements; with electrical resistance heating, pot failure may result in total destruction of the heating elements. The waste heat of flue gases from fuel-fired furnaces may be fed to an adjacent chamber and used to preheat workpieces.

Internally heated furnaces are energized with alternating current at 10 to 15 volts, supplied from a multiple-tap secondary transformer. The molten salt is an electrical conductor and heat is generated within the salt between the electrodes, from resistance to the passage of current. By closely spacing the electrodes, an electromagnetic stirring action of the salt is obtained that assists in maintaining temperature uniformity and a control of ±5 F.

Pot Materials. In salt bath brazing furnaces, the material used for construction of the pot depends on the type of salt that will be contained in it. The submerged-electrode furnace, which has a refractory brick lining, is not suitable for use with cyanide salts or water-soluble carburizing salts containing sodium carbonate or sodium cyanide, because of the rapid erosive effects of these chemicals on the lining of this type of furnace.

Because the salt pot of an externally heated furnace is ordinarily supported from a flange, as shown in Fig. 1(a) and (b), the pot size is limited by the strength of the material used. Externally heated pots for use with all types of brazing salt are made of metals ranging in composition from low-carbon steel to high-nickel-chromium alloys. A small furnace with a pot 10 in. in diameter and 12 in. deep would contain about 43 lb of salt; a fairly large furnace with a pot 24 in. in diameter and 30 in. deep would have a capacity of 700 lb of salt.

With internally heated furnaces, a ceramic (refractory) pot is usually preferred for neutral chloride salts and fluxing salts that consist of neutral chloride salts plus a fluxing agent such as borax or cryolite. Slight modifications can be made in the pot material when neutral salts and salts containing flux are used. When carburizing or cyaniding, in addition to brazing, is to be done, a steel or heat-resisting alloy pot must be used.

Salts

The types of salts used in dip brazing of carbon and low-alloy steels are: (*a*) neutral chloride salts, (*b*) neutral chloride salts plus a fluxing agent such as borax or cryolite, and (*c*) carburizing and cyaniding salts, which are also fluxing types of salts. Types and compositions of brazing salts and temperatures used for brazing of carbon and low-alloy steels with various filler metals are given in Table 1. (See also the safety precautions on page 660.)

Neutral salts, so called because normally they do not add or subtract anything from the surface of the steel being treated, protect the surface from attack by oxygen in the air. However, oxide on the workpiece cannot be reduced by the salt, and a flux must generally be provided.

The neutral salts are mildly oxidizing to steel when they are used at recommended austenitizing temperatures. The oxides produced by heating steel in molten salt are largely soluble; hence, the steel is scale-free after heating. However, the accumulation of oxide in the molten salt progressively makes the salt more strongly decarburizing, and for this reason baths must be rectified periodically, as discussed on page 225 in the article "Heat Treating of Tool Steel", in Volume 2 of this Handbook.

Flux that is applied to the surface of the assembly and dried before the assembly is immersed in the neutral salt will be quickly dissipated by dissolving in the salt or escaping from the surface of the bath as a volatilized salt, or gas. For this reason, there is generally no difficulty in removing flux from an assembly that has been brazed in a salt bath.

*For committee list, see page 593.

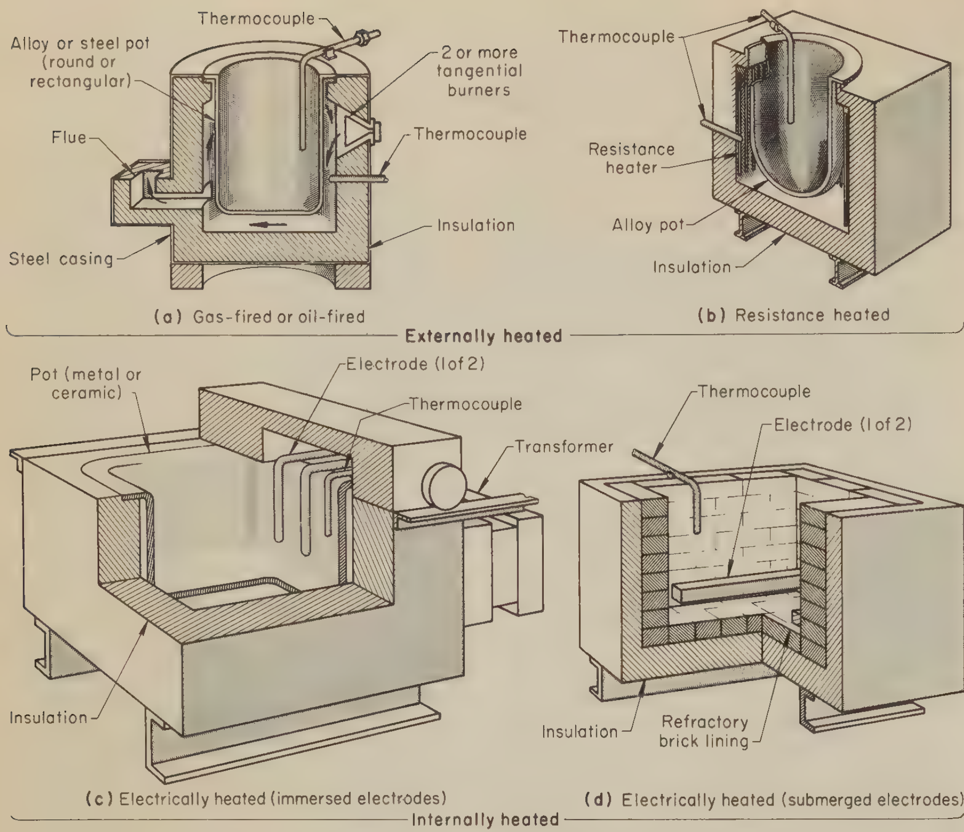

Fig. 1. Principal types of furnaces used for salt bath brazing

Fluxing agents such as borax and cryolite are added to neutral chloride salts to produce a fluxing environment in the bath. When these fluxing agents are used with silver alloy or copper-zinc filler metals, periodic flux additions are required, to maintain the fluxing potential of the bath. When the bath is operating at temperatures above 1200 F, the fluxing potential can be decreased rapidly by oxidation from contact with air or with the parts being brazed, and the fluxing agent must therefore be more frequently replenished. Sometimes a neutral chloride bath is used and the assembly prefluxed.

Carburizing and cyaniding salts provide their own fluxing action. In addition, they supply carbon and nitrogen to the surface of the steel assembly as it is being brazed. Although silver brazing alloys have been used successfully, RBCuZn-A filler metal is generally preferred. A case depth up to 0.012 in. can be obtained without adversely affecting the quality of a joint brazed with this copper-zinc filler metal. The following example describes the use of a carburizing salt bath for both carburizing and brazing. Cyaniding and carburizing in salt baths (without brazing) are discussed in detail in the articles "Cyaniding (Liquid Carbonitriding)", pages 129 to 132, and "Liquid Carburizing", pages 133 to 145, in Volume 2 of this Handbook. Also, see Table 1 on page 65 of Volume 2 for information on the use of salt baths.

Example 607. Combining Brazing and Carburizing in a Salt Bath (Fig. 2)

The 1010 steel assembly shown in Fig. 2 was part of a pair of adjustable self-clamping pliers. The jaw and a threaded bushing for the adjustment mechanism were brazed to the handle in a salt bath that, simultaneously with brazing, also carburized the bushing and handle.

The jaw was first separately carburized for 30 min in a water-soluble carburizing salt at 1675 F to obtain a deeper case than would be obtained in the time allowed for brazing. After being air cooled to room temperature, the jaw was washed and dried.

A hairpin-clip preform of RBCuZn-A copper-zinc filler metal and a tab on the carburized jaw were pressed in place in the handle, and the bushing with a preform ring of the same filler metal was pressed into the opposite end of the handle. Twenty-four assemblies were then loaded on a rack so that the jaws were held in place by the weight of the handles, as shown in Fig. 2. An interference fit held the bushing and handle together.

The rackload of assemblies was brazed and carburized by immersing for 20 min in a water-soluble carburizing salt bath at 1675 F, which also provided the fluxing action. The brazed assemblies were quenched directly in oil and then tempered until the jaw hardness was Rockwell C 48 to 51. The total case depth obtained on the jaw in the two carburizing operations was 0.010 to 0.012 in. A file-hard case about 0.004 to 0.005 in. deep was also developed on the threaded bushing and handle, which provided a hard wear-resistant surface to serve as a base for hard chromium plating.

Fluxes

An adequate fluxing environment is needed to assure good flow and penetration of the brazing alloy in salt bath brazing. When brazing is done in a neutral chloride salt bath, a flux is usually applied to the assemblies before brazing. Flux generally need not be applied to the assembly when using a cyanide bath or other fluxing bath.

Flux can be applied by brushing, dipping, or spraying the parts to be brazed before, during, or after assembly. After flux application, the assemblies must be preheated to dry them before immersion in the salt bath if there is any moisture present.

Typical fluxes employed for prefluxing carbon steels and low-alloy steels that are to be brazed in a salt bath are AWS types 3A and 3B.

Filler Metals

The brazing filler metals shown in column 1 of Table 1 are the most widely used for salt bath brazing of carbon and low-alloy steels. Although silver alloys BAg-13 and 13A (not shown in Table 1) can be used for brazing in a salt bath, they have been supplanted in most applications by copper-zinc alloys, which are less costly and have similar brazing temperature ranges. The rapid heating rate of steel in a salt bath minimizes dezincification of copper-zinc alloys, which facilitates the use of these alloys.

Although a temporary insulating cocoon of frozen salt forms instantly around a piece of cold metal when it is immersed in a salt bath, the temperature of a salt bath can, nevertheless, exceed the melting temperature range of the filler metal before the steel workpieces have reached a temperature high enough for proper wetting to take place. When this occurs, the molten filler metal will flow away from the joint with no brazing. It is therefore desirable to place the filler metal inside the joint in grooves, recesses, or drilled holes (Fig. 3 shows a recess type of arrangement). However, many assemblies of thin-section steel have been brazed successfully with the filler metal placed on the outside of the joint (see Fig. 5).

The brazing filler metal must be in contact with the joint. Filler metals in the form of wire, strip, powder, paste, and cladding are available. Special preform rings or other shapes can be obtained for specific joint requirements.

Joint Design

The filler metal providing the bond in brazed joints is drawn by capillary action between closely adjacent, substantially symmetrical surfaces. A diametral clearance of 0.001 to 0.003 in. is considered necessary for good flow and penetration of silver or copper-zinc filler metals in most joints. For copper brazing, joint clearance can range from a slight interference fit to a positive diametral clearance of about 0.002 in. When brazing dissimilar metals of differing coefficients of thermal expansion or dissimilar masses of the same metal, the design must take into account the differing rates of expansion so that the required joint clearance is obtained between the components at the brazing temperature.

For brazing, lap joints designed for shear loads are preferred to butt joints designed for tensile loads. Six designs for brazing using lap joints are compared with their counterparts commonly used for welding in Fig. 31 in the article on Furnace Brazing. For additional discussion of joint fit and design, the reader is referred to pages 607 to 610 in the same article.

Preparation for Brazing

Burrs can interfere with the capillary action and should be removed. The joint surfaces must be free of grease, oil, paint, oxide and scale that would prevent the filler metal from wetting the workpiece surfaces. (For cleaning methods, see page 602 in the article on Furnace Brazing, in this volume.)

Fluxing, as mentioned previously in this article, can be done before, during, or after assembly, as convenient, but the assembly must be warmed to eliminate any moisture before brazing.

Assembly. An assembly of self-jigging joints minimizes fixturing so that a hook, rod, basket, or rack may be all that is required to support the assembly during the brazing process. Methods of self-jigging are shown in Example 607 (gravity locating and press fitting), in Example 608 (thread joining) and in Example 610 (swaging). These and other methods are illustrated in Fig. 15 in the article on Furnace Brazing and discussed on pages 603 and 604 in that article.

Although the fixturing of workpieces that cannot be self-jigged creates such problems as distortion, difficulty in maintaining dimensional tolerances, and the need for heating an added mass of material, these difficulties can be overcome by careful fixture design, use of a fixture material of thermal expansion compatible with that of the work metal, and attention during brazing so that tolerances are maintained. The fixture material should also be compatible with the salt and flux used and have reasonably long life. The design of the fixture should facilitate draining after removal from the bath.

Preheating an assembly before brazing serves several purposes. If prefluxing is used, preheating dries the flux and vaporizes all moisture from the assembly and fixture. (Even a slight amount of moisture can cause spattering in contact with molten salt.)

Drying in an oven at 400 to 600 F before the assembly is immersed in the molten bath is recommended. However, warming of assemblies to about 200 F by laying them on top of the salt bath furnace is also done.

Preheating of assemblies will decrease the temperature drop of the salt bath and reduce brazing time, and can minimize the premature melting of externally placed filler metal. In joining an assembly consisting of both heavy and light sections, preheating reduces thermal gradients and subsequent distortion, as well as improving the wetting action on the heavier parts.

The preheating temperature must be lower than the solidus temperature of the filler metal and, when brazing carbon and low-alloy steels, is often several hundred degrees lower. In Example 609, the parts were preheated to about 1000 F prior to brazing with BAg-3 filler metal, which has a solidus temperature of 1170 F.

Brazing

General ranges of brazing temperature that are used with various salts are listed in the last column of Table 1 (this page); specific brazing ranges

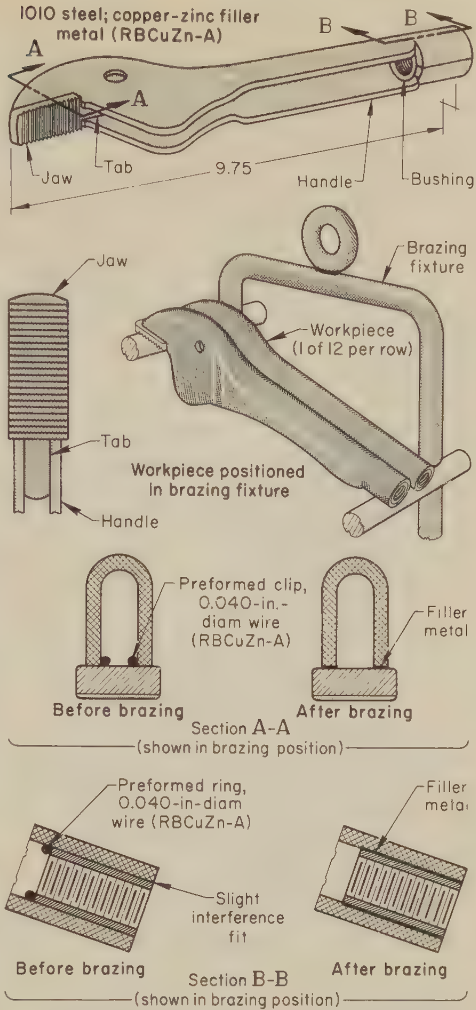

Fig. 2. Self-clamping-pliers part brazed in a salt bath (Example 607)

for the individual filler metals are given in Table 1 on page 627 in "Torch Brazing of Steel", and in Table 3 on page 599 in "Furnace Brazing of Steel".

The time in the molten salt bath differs from one job to another. For thin-section parts to be brazed only, the holding time may be as short as one minute. For assemblies that are to be case hardened as well as brazed, the holding time is the time required to produce the desired depth of case.

After the workpieces have been in the bath for the required time, they are carefully lifted from the salt bath. A uniform motion is necessary during removal from the bath; jerky movements can cause the liquid filler metal to be displaced from the joint.

Brazing and Heat Treating. It is possible to combine brazing with a heat treating operation such as neutral hardening or carburizing; the assembly can be air cooled to room temperature or quenched in a suitable liquid medium, as required.

If the assembly is to be quenched, it should cool in air until the brazing filler metal has fully solidified, before quenching. Otherwise, the filler metal will usually be blown out of the joint during quenching. This is more likely with water quenching than with oil quenching.

When molten salt baths are used for quenching, it is imperative that the salt used for the quenching bath be compatible with the salt used for the brazing and austenitizing bath. Neutral chloride salts are recommended for the brazing and austenitizing salt when a nitrate-nitrite salt is to be used as a quenching bath. The assembly must be air cooled until the filler metal solidifies before quenching in a nitrate-nitrite bath, as the molten salt will react with molten filler metal.

In the two examples that follow, salt baths were used to heat the assemblies for austenitizing and quenching. In the first example, the entire assembly was immersed and brazing was accomplished in the bath. In the second example, the assembly was only partially immersed, the joint being heated by conduction from the immersed portion. In addition, the joint clearances were considerably greater than those customarily used for brazing.

Example 608. Use of a Salt Bath To Braze and Harden in One Treatment (Fig. 3)

The breech-bolt assembly shown in Fig. 3 was brazed with a silver alloy filler metal and heated for hardening in one treatment.

Originally, a copper filler metal was used and brazing was done in a controlled-atmosphere furnace, but the bolt was completely annealed during furnace brazing and required subsequent hardening. After a preliminary investigation, it was found that this assembly could be brazed at the same time it was being heated for hardening in a salt bath.

The bolt assembly consisted of a bolt body of 1137 steel and a handle and guide lug of 1120 steel. The unit was assembled by placing a ring of BAg-1 filler metal in the bottom of the guide lug adjacent to the bolt body, and then screwing the handle

Table 1. Typical Salts Used for Salt Bath Brazing of Carbon and Low-Alloy Steels With Various Filler Metals

Filler metal(a)	Type of salt	Nominal composition, %	Brazing temperature range, F
BAg-1 through BAg-8, and BAg-18	Neutral	55 $BaCl_2$, 25 NaCl, 20 KCl	1150 to 1600
	Cyaniding-fluxing	20 to 30 Na_2CO_3, 20 to 30 KCl, 30 to 40 NaCN	1200 to 1600
	Neutral	50 NaCl, 50 KCl	1350 to 1600
RBCuZn-A	Neutral	80 $BaCl_2$, 20 NaCl	1675 to 1725
	Fluxing	79 $BaCl_2$, 20 NaCl, 1 borax	1675 to 1725
	Carburizing-fluxing (water soluble)	30 NaCl, 30 KCl, 20 carbonate, 15 to 20 NaCN, activator (proprietary)	1675 to 1725
RBCuZn-D	Neutral	90 $BaCl_2$, 10 NaCl	1900 to 1925
BCu-1 and 1a	Neutral	95 $BaCl_2$, 5 NaCl	2000 to 2100
	Neutral	100 $BaCl_2$	2000 to 2100

(a) For nominal compositions and brazing temperature ranges, see Table 1 on page 627 in "Torch Brazing of Steel" for silver alloys and copper-zinc alloys, and see Table 3 on page 599 in "Furnace Brazing of Steel" for copper filler metals. (b) Temperatures shown are those of the salt bath.

through the lug snugly into the threaded hole in the bolt body. This method of assembly held the filler metal in place so that, after brazing, the handle, lug, and bolt body would all be joined by brazing. The joints were coated with type 3A flux and dried by heating to 400 to 500 F.

The bolt assembly was then immersed in a salt bath for 7 min at 1550 F. The bath was a neutral chloride salt mixture containing 50% NaCl and 50% KCl. The bolt body was austenitized at the same time the filler metal penetrated the joints to be brazed. The assembly was immediately transferred to a nitrate-nitrite salt bath at 500 F for 7 min.

In this application, it was unnecessary to permit the filler metal to solidify before the quench; any exposed molten filler metal that was oxidized by the quench was removed in a later machining operation. The parts were then air cooled, tempered in a nitrate-nitrite bath at 820 F for 20 min, air cooled, and washed in hot water. The final hardness of the bolt body was Rockwell C 30 to 34, and the strength and quality of the brazed joint were completely satisfactory.

Example 609. Joining Carbide Tips to Tool Bits While Heating the Tool Bits for Hardening (Fig. 4)

Carbide-tipped rock bit drills, shown in Fig. 4, were joined using a silver brazing filler metal and heated for hardening in one operation in a salt bath. The bits ranged in diameter from 6 to 9 in. and weighed 100 to 300 lb. The shanks were made of air-hardening or oil-hardening tool steels.

Shanks and tips were vapor degreased and the surfaces to be joined were grit blasted and coated with flux. The carbide tips were inserted into the slots in the ends of the shanks with BAg-3 alloy shims placed under and on each side of each tip. Metal plates welded to the outer end of each slot, as shown in Fig. 4, kept flux and molten filler metal from escaping and kept the molten salt from entering when the assemblies were heated. (The plates were removed later by machining.)

The assembled bits were placed in a fixture with the carbide-tipped ends up, and were preheated to about 1000 F to dry the flux and assembly and to reduce the time required to reach austenitizing temperature in the salt bath. Each assembly was then partially immersed in the salt bath to a level at which the metal plates welded on the ends of the slots would safely prevent molten salt from entering the joint area. The assemblies were held in the bath for 20 to 30 min, depending on the size of the bit. This time period was needed to austenitize the shank and was not necessarily required for the joining operation. The tips were not submerged for three reasons:

1. To avoid thermal shock that might crack the carbide
2. To avoid washing away the flux
3. To keep the joints visible and accessible so that dry powdered flux and filler metal could be added to fill the joint.

The bath, a neutral chloride salt (50% NaCl, 50% KCl), was maintained at selected temperatures between 1600 and 1650 F, and held within ±5 F. The exposed ends of the assemblies, containing the joints being brazed, were heated only by conduction from the immersed portion. This lower heat input and the heat losses by radiation from the exposed metal served to keep the temperature in the joint area within the range (1270 to 1500 F) required to prevent overheating of the high-cadmium filler metal.

The assembly was air cooled or oil quenched, depending on the type of tool steel in the shank. During the cooling period, additional filler-metal rod and dry powdered flux were fed into the molten pool of BAg-3 alloy to fill the voids left by the approximately 20% shrinkage of the filler metal during solidification. After cooling, any salt remaining was washed from the bit, which then was tempered to the hardness specified for the shank.

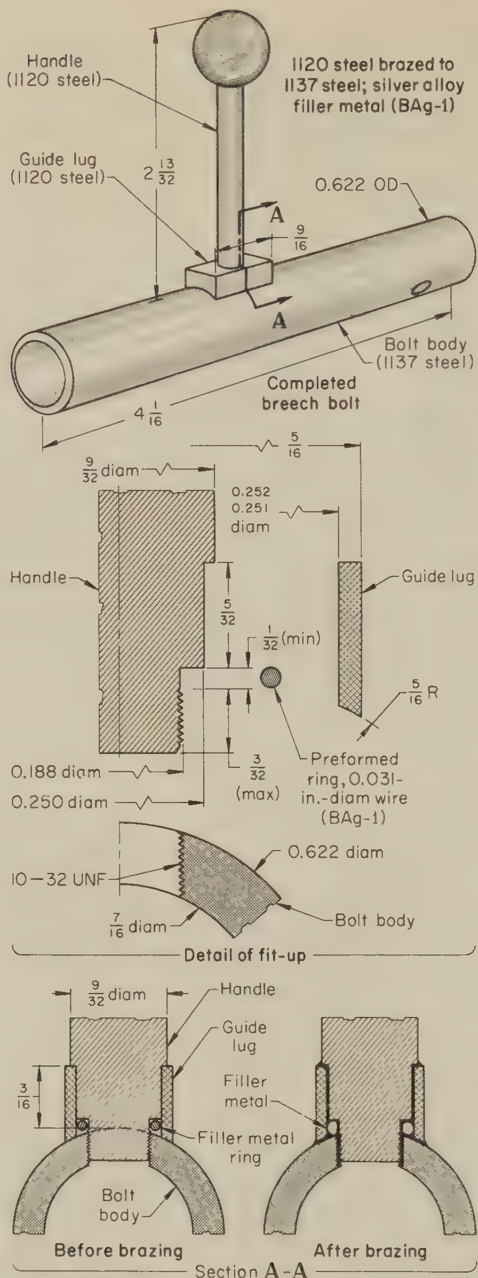

Fig. 3. Rifle breech-bolt assembly that was simultaneously heated for hardening and brazed in a salt bath (Example 608)

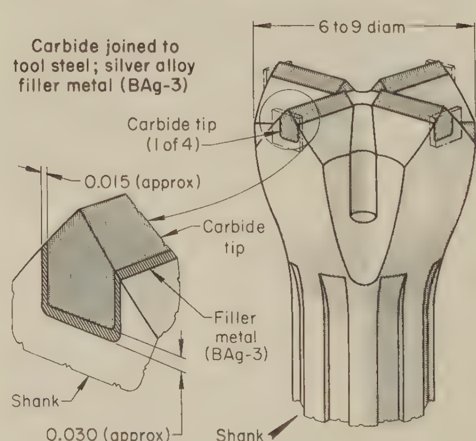

Fig. 4. Carbide-tipped rock bit that was joined using silver brazing alloy and simultaneously heated for hardening by partial immersion in a salt bath (Example 609)

The larger-than-normal clearances for filler metal (0.015 in. on each side and 0.030 in. under the carbide inserts) were found by field experience to provide a shock-impact cushion between the carbide and steel, which reduced the likelihood of premature failure.

Salt bath heating was selected because the rapid heating minimized oxidation and prevented breakdown of flux. In addition, several assemblies could be processed at one time.

Induction heating was rejected as a means of performing the operation because capacity would have been limited to one rock bit per station; high heat input would have demanded diffusion cycles to allow heat to be conducted from the surface to the interior of the heavy bits; temperature would have varied considerably in the carbide area, causing erratic melting and too many voids; overheating of carbide would have caused cracking; and subsequent over-all heating would have been necessary to harden the shank.

Torch brazing would have been unsatisfactory because: (*a*) uneven heating would have caused erratic melting of filler metal; (*b*) with localized heating, the whole bit would have required reheating to harden the shank; (*c*) flames from the various torches would have interfered with the operator's ability to monitor the joint and to face feed the filler metal after heating was completed; and (*d*) the torch flames would have caused excessive scale and spent flux, which would have had to be removed.

Use of cyanide salts in brazing baths allows carburizing, cyaniding or austenitizing to take place during brazing. However, the correct quenching medium must be chosen.

Safety Precaution. *The introduction of cyanide salts or other reducing agents into a nitrate-nitrite quenching bath will cause violent explosions.*

Because assemblies that are being brazed in salts containing cyanide must not be quenched in nitrate-nitrite salts because of the explosion hazard, and because the filler metal must solidify before quenching, the following procedure has been used:

A brazing filler metal such as RBCu-Zn-A is selected that will solidify above the transformation temperature range of the steel being brazed. The brazed assembly is transferred from the cyanide-containing bath into a neutral chloride salt bath rinse that is maintained below the solidus temperature of the filler metal but within the austenitizing range of the steel. The assembly is then transferred from the neutral chloride rinse to the nitrate-nitrite bath for the quenching operation. It is essential to control the amount of cyanide buildup in the neutral chloride rinse bath. When tests indicate more than 5% cyanide in the chloride rinse, part of the chloride salt should be discarded and the remainder diluted with the addition of new neutral chloride salt.

After quenching in the nitrate-nitrite bath, the assemblies are air cooled, washed, and then tempered, if tempering is required.

All fixtures must be thoroughly cleaned and dried after the quenching operation, to prevent transfer of nitrate-nitrite salt to cyanide baths or neutral chloride baths. Nitrate-nitrite salts will cause an explosion if mixed with cyanide, and a chloride bath contaminated with nitrate-nitrite salts will produce pitting and decarburization of steel parts immersed in it.

Further safety precautions applicable to the operation of nitrate-nitrite salt baths are presented on page 38 in Volume 2 of this Handbook.

Mechanized Brazing

The salt bath brazing process can be mechanized to increase production rates. Either semiautomatic or fully automatic handling mechanisms can be used, such as those described in the article on "Liquid Carburizing", page 139, in Volume 2 of this Handbook. A simple automatic arrangement is the "merry-go-round" described in Example 610, which follows. In this type of machine, the time at each station is the same. Different automatic arrangements have been used with conveyors to lift the workpieces in and out of the various furnaces and tanks in the line. One uses a bar and arm, from which the workpieces are suspended; another is the "jackrabbit" mechanism described in the referenced article. These and semiautomatic monorail transfer systems have the advantage that they can be set up with furnaces and tanks of different lengths so that the workpieces are held at each station for different lengths of time. A conveyorized production line was used in Example 611, which also follows.

Example 610. Partial Immersion of Assemblies During Brazing, To Preserve Work-Hardened Areas (Fig. 5)

Bicycle-fork assemblies made of 1010 steel were brazed in a salt bath using RBCuZn-A filler metal. Selective heating by partial immersion was necessary to retain, as nearly as possible, the strength developed in the side tubes by cold working. This was accomplished by suspending the fork so that only the stem tube, reinforcing plates and a portion (2¾ in.) of the side tubes were immersed in salt (see Fig. 5).

Originally the forks had been brazed in two gas-fired pots containing molten brass. The forks were preheated by laying them on top of the furnace and then were dipped in the molten brass, one fork at a time. A high degree of operator skill and rapid manipulation were required. Production rate was 75 forks per hour. Because loose fits (up to 1⁄32-in. clearance) were used, it was necessary to tack weld the assembly before brazing, to make it self-supporting. Rejects ran 2% and were not reworkable. Salt bath brazing was then tried.

A copper-zinc alloy, rather than copper, was selected as filler metal for salt bath brazing because copper-zinc permitted greater variation in joint clearance without sacrifice in joint strength, and the joint strength was about the same for both filler metals, although the brazing temperature with the copper-zinc alloy was lower (1700 F vs 2050 F). The lower brazing temperature required less heat and also minimized grain growth in the steel base metal.

The bicycle fork shown in Fig. 5 was assembled with the copper-zinc filler-metal rings in place and was made self-jigging by swaging the tubes into the reinforcing plates. To maintain alignment of the side tubes, a threaded rod with wing nuts was fastened in the slots at the hub end of the side tubes. This rod also provided the means of suspension. The joints were fluxed before brazing.

Because of the production requirements, brazing was done in a "merry-go-round" brazing machine, shown schematically in Fig 5. The machine consisted of six stations, with each station accommodating a fixture from which up to 14 fork assemblies were suspended. The fixtures were raised, lowered and indexed by arms that connected them to a central hydraulic cylinder. Time at each station was 3 min, with a 30-sec transfer time between stations.

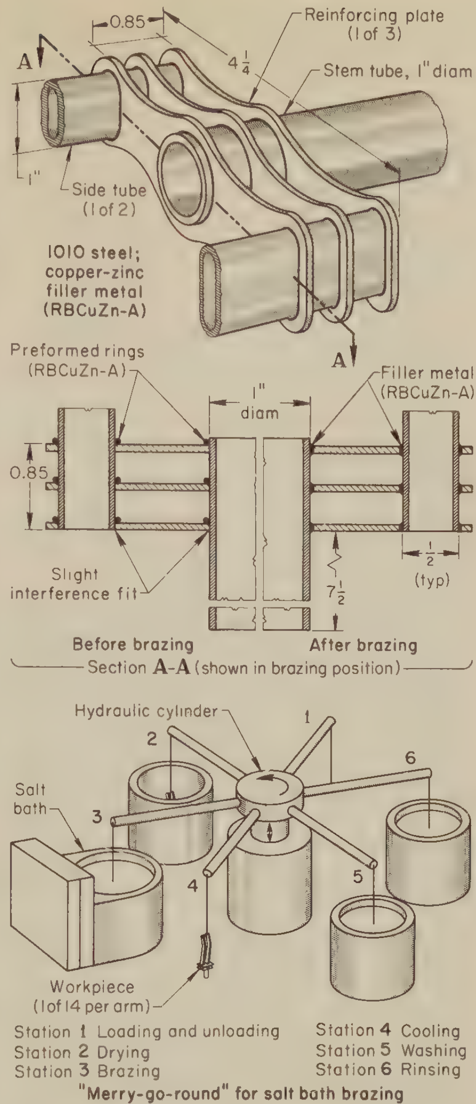

Fig. 5. Bicycle-fork assembly for which cost was reduced and production rate increased by changing from dip brazing one at a time in a bath of molten filler metal to mechanized brazing 14 at a time in a salt bath (Example 610)

Forks were hand-loaded and unloaded at the first station. Assemblies were dried at station 2 in a 5-kw electric drier. The salt bath brazing furnace at station 3 was an internally heated immersed-electrode furnace operated at 1700 F, using a neutral chloride salt composed of 80% $BaCl_2$ and 20% NaCl. Air cooling to solidify the filler metal followed at station 4. Stations 5 and 6 were a hot water wash and a hot water rinse. Unloading completed the cycle.

The new method increased production from 75 to 240 forks per hour, and resulted in a net saving of 7¢ per fork. Less than 1% of the forks showed defects, and these were salvaged by reworking.

Example 611. Use of Salt Bath Brazing for High Production (Fig. 6)

Steel tube-and-collar assemblies of various sizes from ¼ to 4 in. in outside diameter, one of which is shown in Fig. 6, were originally joined by induction brazing with silver alloy filler metal. Increased demands for the hydraulic systems in which these assemblies were used exceeded the capacity of the existing production facilities. As there were more than 20 sizes and some irregular shapes, the additional induction brazing equipment that would have been necessary to meet the production requirements was found to require an excessive equipment cost.

An attempt to braze the assemblies with copper filler metal in a controlled atmosphere furnace was only partially successful. The furnace was able to produce the needed quantity of work, but the much higher temperature required for copper brazing caused the tubes to warp enough so that they did not properly fit the mandrels that were used in a subsequent bending operation.

A production line for salt bath brazing was set up, consisting of an overhead conveyor that carried the assemblies through preheat, salt bath brazing and quenching operations. The shape of the production line was elliptical, to conserve floor space. The fixtures were made of type 304L stainless steel and were of a simple design suitable for holding tubes of a variety of sizes.

Production rate for salt bath brazing was 400 assemblies per hour, compared with 30 assemblies per hour using the original induction heating setup.

Before preheating and brazing, all parts were degreased (and pickled if necessary) and were placed on a wide-belt conveyor, which carried the parts through stations where all joints were flux coated, the parts assembled, and the assemblies hand loaded onto the brazing conveyor. A borax-base type 3A flux was applied by brushing.

The filler metal used was a silver alloy (50% Ag, 22% Cu, 20% Zn, 7% Cd, 1% Sn) having a solidus of 1125 F and a liquidus of 1145 F. Assembly consisted of placing a preformed ring of 0.062-in.-diam filler-metal wire in the collar and inserting the tube, as shown in Fig. 6. The filler-metal ring was confined by a bevel on the end of the tube so that it would be retained during the brazing operation. A diametral clearance of 0.001 to 0.003 in. was maintained between the collar and the tube. The tubes were gravity located in the collars (a self-jigging joint) and the fixture was limited to holding the collar and giving lateral support to the tube.

Gas burners were used to preheat the assemblies to dry them. The preheat temperature was about 500 F.

The assemblies were partially immersed (the joint area only) in the salt bath and held until they reached bath temperature.

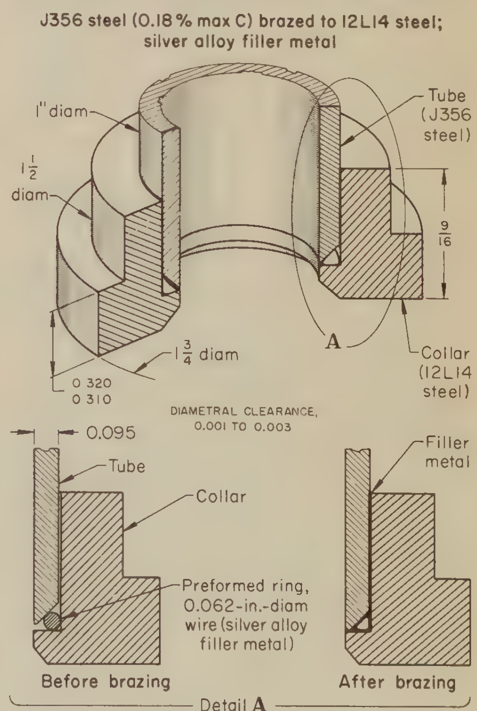

Fig. 6. Tube-and-collar assembly that was salt bath brazed on a mechanized production line (Example 611)

The salt bath furnace was a submerged-electrode type, 13½ in. wide by 48 in. long by 25 in. deep. The pot was lined with firebrick. A neutral chloride type of salt bath composed of sodium and potassium chlorides was used. The bath was maintained at 1600 F (to minimize dragout) by on-off switching, with an over-temperature alarm. The bath was rectified, when needed, by bubbling methyl chloride gas through it. Fumes from the bath were exhausted for pollution control.

After brazing, the assemblies were quenched in cold water and hand unloaded from the conveyor. The quench provided enough cleaning, since the assemblies were to be pickled and plated after bending. This same brazing procedure was used for low-carbon, high-carbon and alloy steels.

Safety Precautions

Cautions and references for the safe use of nitrate-nitrite salt baths and oil quench tanks, and for the need for all parts to be free of moisture before immersion in a salt bath, have been included earlier in this article. The same protective equipment for personnel suggested on page 145 in Volume 2 of this Handbook applies to all salt bath operations and includes long heat-resisting gloves, an asbestos apron, and a face shield or safety glasses, or both.

Salt bath brazing may produce dusts, fumes and gases hazardous to health. Therefore, adequate exhaust systems and ventilation are necessary. For example, cadmium is contained in some silver alloy filler metals. Cadmium oxide fumes are toxic, and inhalation of these fumes can be fatal. Other metals, salts and materials present various degrees of hazard.

The fluorides in fluxes pose a dual problem: It is necessary not only to provide adequate ventilation to carry away fumes, but also to avoid skin contact with these fluxes and to provide means to make it unnecessary for anyone to place his hands in the flux.

Table 2. Threshold Limit Values (TLV) for Substances Encountered in Salt Bath Brazing
(See text for discussion of TLV)

Substance	TLV, mg per cubic meter(a)
Barium (soluble compounds)	0.5
Cadmium oxide fume	0.1
Copper dusts and mists	1.0
Cyanide (as CN) — Skin(b)	5.0
Fluoride (as F)	2.5
Hydrogen cyanide — Skin(b)	11.0
Hydrogen fluoride	2.0
Silver metal and soluble compounds	0.01
Zinc oxide fume	5.0

Source of data and text summary: "Threshold Limit Values of Airborne Contaminants and Intended Changes Adopted by ACGIH for 1970", American Conference of Governmental Industrial Hygienists, Cincinnati, Ohio 45202.

(a) Approximate milligrams of particulate per cubic meter of air. (b) "Skin" following a substance indicates that the substance can penetrate the skin to cause systemic effects.

Brazing personnel should thoroughly wash their hands before making any body contacts or handling food.

Two brazing salts listed in Table 1 contain cyanide. If taken internally, cyanides are fatally poisonous; if allowed to come in contact with scratches or wounds, they are highly toxic. Fatally poisonous fumes are evolved when cyanides are brought into contact with acids. To avoid possible toxic effects, it is recommended that an exhaust system be provided to remove the fumes from salt baths. Precautions in the use of cyanide salts and the disposal of cyanide wastes are discussed further on page 145 in Volume 2 of this Handbook.

Threshold limit values (TLV) of airborne concentrations of substances commonly encountered in salt bath brazing are given in Table 2. A summary of some of the limitations of these values follows, but the reader is directed to the reference in Table 2 for complete information. Threshold limit values represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse effect. They are time-weighted concentrations for a 7-or-8-hr workday and a 40-hr week. They should be used as guides in the control of health hazards, but not as fine dividing lines between safe and dangerous concentrations.

These values are intended for use in the field of industrial hygiene and should be interpreted and applied only by persons trained in that field. They are *not* intended for use, or for modification for use: (*a*) as a relative index of toxicity or hazard, (*b*) in the evaluation or control of community air pollution or air-pollution nuisances, (*c*) in estimating the toxic potential of continuous, uninterrupted exposures, or (*d*) as proof or disproof of an existing disease or physical condition.

References. In addition to the reference in Table 2 and the article on cyanide baths in Volume 2, the reader is referred to the following sources of detailed information on safe practices, cautions and hazards in brazing:

Other Examples of Salt Bath Brazing

Examples of salt bath brazing presented elsewhere in this volume describe joining of: malleable iron to 1010 steel (Example 614); type 304 stainless steel to copper alloy 230 (Example 630); aluminum alloy 6061 (Example 632); and copper alloy 220 to cast bronze (Example 661).

Brazing of Cast Irons

BRAZING gray, ductile and malleable cast irons differs from the brazing of steel in two principal respects: (*a*) special precleaning methods are necessary to remove graphite from the surface of the iron, and (*b*) the brazing temperature is kept as low as feasible, in order to avoid reduction in the hardness and strength of the iron.

The processes used for brazing cast irons are the same as those used for brazing steel — furnace, torch, induction and dip brazing. As with other metals, selection of the brazing process depends largely on the size and shape of the assembly, the quantity of assemblies to be brazed, and the equipment available. For information on brazing equipment and general procedures, see the articles on pages 593 to 660 in this volume.

Filler Metal and Flux. Because most cast irons are brazed at relatively low temperatures, the filler metals used are almost exclusively silver brazing alloys. Compositions and other information concerning the more common silver alloy filler metals are listed on page 610 in the article on Furnace Brazing in this volume. Of these silver alloys, BAg-1 is most often used for brazing of cast iron, mainly because it has the lowest brazing-temperature range. A fluoride-type flux such as AWS type 3A is usually used with BAg-1 filler metal.

Brazeability

Relatively high silicon content and sand inclusions on as-cast surfaces have some adverse effects on the brazeability of cast iron, but these effects are less significant than the adverse effect of graphite, which is present in all gray, ductile and malleable cast irons. Graphite has essentially the same effect on machined joint surfaces as on as-cast surfaces. Although gray, ductile and malleable irons all have lower brazeability than carbon or low-alloy steels, the three types of iron are not equal in brazeability.

Malleable iron is generally considered the most brazeable of the three common types of cast iron, largely because the total carbon content is somewhat lower (seldom over 2.70%), and because the graphite occurs in the form of approximately round nodules and thus is easier to remove or cover up (as by abrasive blasting). Also, malleable iron is lower in silicon than the other types of cast iron, which makes it better suited for brazing.

Ductile iron can have a composition nearly the same as gray iron, but the graphite particles are spheroidal rather than flake-shape. The spheroidal shape is more favorable for brazing. Shot or grit blasting is effective in rolling metal over graphite particles that are exposed at the surface.

Gray iron, which is characterized by large flakes of graphite, is the type of cast iron most difficult to braze. Until the development of electrolytic salt bath cleaning, brazing of gray iron was considered impractical.

Applicability

Brazing is sometimes used to repair defective or damaged castings, although braze welding is more often used for this purpose (see the article on Oxyacetylene Braze Welding of Steel and Cast Irons, which begins on page 579 in this volume).

Most brazing of cast iron is done to join assemblies at lower cost than is possible by another process, or to fabricate parts that are difficult to produce as one-piece castings (see Example 612). In some applications, two or more cast iron components are brazed together; in other applications, one or more components of a brazed assembly are made of another metal — most often, of steel (see Examples 613 and 614). Copper alloys and cast iron can also be joined by brazing with silver alloy filler metal.

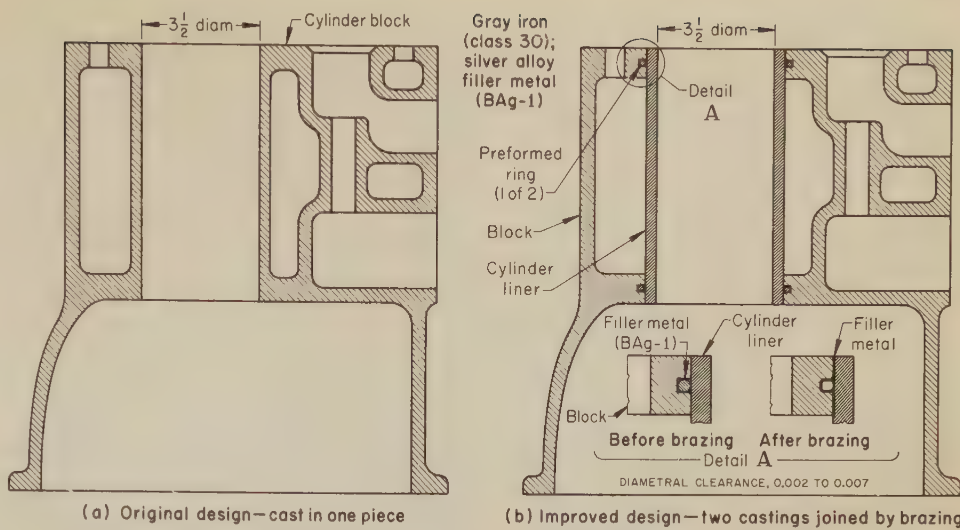

Fig. 1. Cross sections of gray iron cylinder blocks made originally as a single casting and subsequently by joining two castings by furnace brazing (Example 612)

Preparation of Castings for Brazing

Preferred joint designs for brazing cast iron are generally the same as for steel. Best results are obtained by the use of diametral clearances in the range of 0.002 to 0.005 in. Diametral clearances up to 0.010 in. may be used, but this much clearance will result in lower joint strength and added filler-metal cost.

Methods of Surface Preparation. A number of methods have been tried for preparing cast iron surfaces for brazing; most of them have been only partly successful.

Abrasive blasting with steel shot or grit has proved reasonably successful for preparing the surfaces of ductile and malleable iron castings, but is seldom suitable for preparing surfaces of gray iron castings. Other methods that have been used with only moderate success include a variety of pickling and other chemical treatments, searing with an oxidizing flame, and heating to 1600 to 1650 F in a strongly decarburizing atmosphere.

Electrolytic treatment in a molten salt bath, alternately reducing and oxidizing, has been the most successful method for surface preparation and is applicable to all graphitic cast irons.

Before any procedure for cleaning is adopted, it is advisable to make tests by cleaning samples of the iron that will be used for the castings to be brazed and then fluxing them and applying filler metal (preferably on a smooth, flat surface). The samples are then heated to the pre-established brazing temperature, cooled, and examined visually. If the samples show indication that the filler metal has not uniformly wetted the test piece, the surface is not sufficiently clean.

Electrolytic Salt Bath Cleaning. The cleaning method that has proved most effective as a means of preparing cast iron surfaces for brazing is basically the same as the sodium hydroxide type of descaling described in the article on Salt Bath Descaling, page 357, Volume 2 of this Handbook, except that the bath described in that article is a two-tank system. The salt used for cleaning is sodium hydroxide plus additives.

For cleaning cast iron, the salt bath is usually operated at 850 to 900 F. Direct current is passed through the bath during the process, and by changing polarity, the action of the molten bath can be changed from oxidizing to reducing, or vice versa.

Castings are immersed in the bath, suspended from bus bars or fixtures, which are insulated from the tank that contains the molten salt. Common practice is first to make the castings negative and the tank positive; with this polarity, the action of the bath is reducing. During this portion of the cycle, particles of sand are removed and oxides are reduced. The direction of the current is then reversed and oxidation begins. During this portion of the cycle, graphite is removed from the surface of the castings. The current is again reversed and the cycle is completed under reducing conditions. Castings then are immersed in water, to finish the cleaning and to rinse away the salt, and are dried.

A typical processing cycle is described in greater detail in Example 613 (column 3, this page) and in the table accompanying Fig. 2 (next page).

Preheating. To minimize brazing time and to dry the flux when brazing in a furnace or a salt bath, it may be advisable to preheat assemblies containing one or more cast iron components. As cast irons have moderate to high thermal expansion coefficients, coupled with relatively low thermal conductivities, it may be advisable also to preheat the entire assembly to a temperature between 400 and 800 F before torch or induction brazing, to reduce temperature differences.

Production Applications

The three examples presented in this section deal with the brazing of gray iron to gray iron, gray iron to steel, and malleable iron to steel.

Foundry problems involved in producing complex castings can sometimes be overcome by producing two or more simpler castings and brazing them together. Not only is it difficult to make molds for castings with complex internal passages, but removing the cores and burned-in sand from the castings may be even more difficult. The example that follows describes a typical use of joining two gray iron castings by brazing to replace a complex casting.

Example 612. Brazing Two Castings for an Engine Cylinder Block (Fig. 1)

The gray iron cylinder block for which a sectional view is shown in Fig. 1(a) was originally machined from a single casting. Not only were the cores for the internal passages difficult to mold, but removing the core sand from the casting was an additional problem.

Both difficulties were overcome by changing from the one-piece design to two castings brazed together as shown in Fig. 1(b). Mating surfaces of the block and cylinder liner were finish machined so that diametral clearance was 0.002 to 0.007 in. Two grooves were machined in the block, as shown in Fig. 1(b), to receive the preformed filler-metal wires.

Both of the cast components were then cleaned electrolytically in a molten salt bath. [A procedure similar to that described in Example 613 was employed.]

The two castings were then assembled, with the preformed rings of filler-metal wire (BAg-1) and flux (type 3A) trapped in the grooves, and brazed in a furnace at 1325 F under a protective atmosphere.

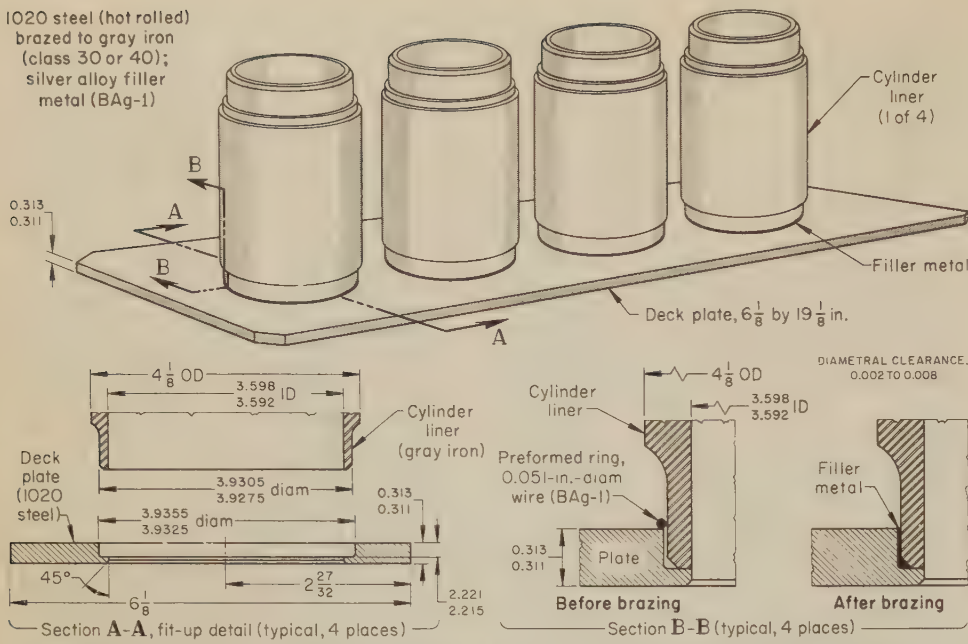
Brazing cast iron to steel may be done to attain a specific set of properties, to simplify the casting process, or to reduce cost. In the example that follows, four gray iron castings were brazed to a wrought steel plate.

Example 613. Brazing Four Gray Iron Cylinder Liners to a Steel Deck Plate (Fig. 2)

The brazed assembly shown in Fig. 2, consisting of four centrifugally cast cylinder liners of class 30 or 40 gray iron and a deck plate of 1020 steel, served as a component of a gasoline engine.

All five parts of the assembly shown in Fig. 2 were machined to the sizes shown, which permitted a diametral clearance of 0.002 to 0.008 in. between each gray iron liner and the steel plate.

In preparation for brazing, the steel plate was cleaned by degreasing in trichlorethylene. The gray iron liners were cleaned electrolytically in a bath of molten salt at 860 F for a total time of 35 min, after which they were immersed first in cold water and then in water at 160 F. (Details of the cleaning equipment and of the processing procedure used are given in the table that accompanies Fig. 2.)



Electrolytic Salt Bath Prebraze Cleaning	
Tank size	4 by 3½ by 4 ft high (usable volume)
Tank capacity	13,000 lb of molten salt
Salt composition	Principally sodium hydroxide
Current	1800-amp dc (reversible polarity)
Bath temperature	860 F
Reduction-oxidation cycle:	
Reduction (workpiece negative), agitator on	5 min
Oxidation (workpiece positive), agitator off	20 min
Reduction (workpiece negative), agitator on	10 min
Total time in bath	35 min
Salt removal:	
Dip hot castings	Cold water
Dip cold castings	Water at 160 F

Conditions for Furnace Brazing	
Furnace	Roller hearth, multiple zone
Electrical heating power	330 kw
Furnace zone length:	
Vestibule	4 ft, 2 in.
Heating zone	22 ft, 6 in.
Slow-cooling zone	10 ft
First water-cooled zone	6 ft, 10 in.
Second water-cooled zone	5 ft, 4 in.
Third water-cooled zone	6 ft, 11 in.
Atmosphere	Exothermic, 6.5-to-1 air-to-gas ratio
Furnace temperature	1300 F
Filler metal	BAg-1
Flux	Type 3A
Brazing time, door-to-door	144 minutes
Production rate	62½ assemblies per hour

Fig. 2. Gray iron cylinder liners furnace brazed to a steel deck plate for a gasoline engine, after being cleaned in an electrolytic salt bath (Example 613)

Immediately after prebraze cleaning, the following fluxing and assembly procedure was used.

1 The deck plate was placed on a carbon block that was supported by the furnace tray.
2 A liner was placed in a fixture that held it at a 45° angle above a pot containing type 3A flux in paste form.
3 A degreased ring of BAg-1 filler metal was placed around the liner ¼ in. from the end to be joined to the plate.
4 Flux was applied to the end of the liner by lowering it into the flux pot as far as the filler-metal ring, and rotating the liner while holding it at a 45° angle. This procedure served to place a uniform coat of flux on the end of the liner for a distance of about ¼ in. from the end.
5 The liner was then removed from the fluxing fixture and placed in one of the holes in the plate (Fig. 2).
6 The filler-metal ring was then pushed down into position against the plate (see section B-B in Fig. 2).
7 A 4½-lb weight was then hung in the liner bore to ensure that the liner would retain its position during brazing.

The above procedure was followed for each liner. The assembly was then brazed by the following procedure.

1 The assembly, on its carbon block and tray, was pushed into the vestibule of a 330-kw multiple-zone roller-hearth furnace.
2 The assembly then entered the heating zone under an exothermic atmosphere at 1300 F, where the brazing was accomplished.
3 From the heating zone, the assembly moved into the slow-cooling zone, then through three consecutive water-cooled zones and was finally removed at a temperature of 300 F maximum.

Total time in the heating zone for each assembly was 60½ min. Soaking at brazing temperature was approximately 15 min. Total time in the furnace for each assembly was 144 min (door-to-door). By following the procedure outlined here, the assemblies were brazed at an average rate of 62½ per hour.

After brazing, each assembly was cleaned ultrasonically in a solution of 10 oz of rust stripper per gallon, rinsed in cold water, and dipped in a solution of 2 oz of alkaline rust preventive per gallon.

Quality of the brazed joints was checked visually by the furnace operator, and verified by fluorescent-penetrant inspection.

The application described in Example 613 is one of numerous similar applications performed in various plants. Details of processing procedure vary considerably among plants, although surface preparation by the use of electrolytic salt bath cleaning is general.

Retention of Strength. Cast irons that contain pearlite or free carbide graphitize and decrease in strength at elevated temperatures. Because graphitization is a function of both time and temperature, some experimentation is usually necessary to develop a brazing cycle that will produce acceptable joints without excessive graphitization and decrease in strength.

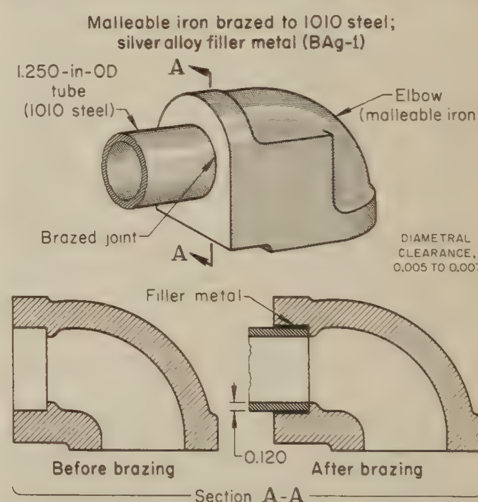
In Example 613, the assemblies were heated for an hour at 1300 F maximum, with no significant decrease in strength. In a similar application, in another plant, the assemblies were heated to about 1450 F without significant decrease in strength. However, in the latter application, heating was by induction instead of in a furnace, and the heating time was very much shorter than would have been required in a furnace.

In some plants using furnace brazing, the furnace is operated at a considerably higher temperature than is desired for brazing (sometimes as high as 1600 F), but using time cycles so short that the assemblies never reach furnace temperature.

For applications in which little or no decrease in the strength of the cast iron can be tolerated, it is mandatory to use a filler metal with as low a flow-temperature range as possible, thus permitting a low brazing temperature, and to keep the time at brazing temperature to the minimum.

The temperature required for wetting the base metal and for flow of filler metal having a melting range of 1145 to 1195 F may vary from about 1275 to 1550 F, depending on the complexity of the joint design, especially the distance the filler metal must flow. Simple joints with short flow distances can be brazed at lower temperatures than more complex joints.

Dip Brazing in a Molten Salt Bath. One of the more common applications for brazing of cast iron is the joining of steel tubing to headers, special fittings and stanchions. Various mechanical assemblies are brazed to cast iron because different metal properties are needed in different parts of the assembly or, more often, because the fitting portion of such an assembly can be



Conditions for Salt Bath Brazing	
Furnace	Pit-type salt bath(a)
Salt	Sodium chloride and potassium chloride(b)
Fixtures	Type 304L stainless steel
Prebraze cleaning:	
Steel tube	Degrease
Cast fitting	Electrolytic salt bath clean(c)
Filler metal	BAg-1
Flux	Type 3A
Brazing bath temperature	1600 F(d)
Time in salt bath	Varied with load(d)
Postbraze cleaning	Water quench

(a) Brick lined, 48 in. long, 13½ in. wide, and 25 in. deep. Heated by three-phase, 60-cycle, 460-volt, 110-kw, submerged electrodes; with on-and-off temperature control and over-temperature alarm. (b) Rectified with methyl chloride to maintain neutrality. (c) See conditions given in table with Fig. 2. (d) Temperature of parts probably did not exceed 1425 F.

Fig. 3. Malleable-iron-to-steel fitting assembly dip brazed in molten salt (Example 614)

made most economically from cast iron. Such assemblies can be satisfactorily brazed by torch, induction, atmosphere furnace, or salt bath processes. Selection of process depends mainly on the quantity to be brazed and the equipment available.

In the example that follows, dip brazing in molten salt was selected for joining a cast fitting of malleable iron to steel tubing, because it was possible to achieve a higher production rate than by other available processes. The particular type and size of fitting assembly discussed in this example is one of many that are joined by brazing. In some larger sizes, the casting is made of gray or ductile iron instead of malleable iron.

Example 614. High-Production Dip Brazing of Malleable Iron Fittings to Steel Tubing (Fig. 3)

Malleable iron elbow castings, like the one shown in Fig. 3, were used to connect hydraulic pressure lines of 1010 steel tubing to standard ports.

Diametral clearance of 0.005 to 0.007 in. between the tube and the casting was maintained by boring the casting holes; this clearance ensured good capillary flow of the silver alloy filler metal. Free graphite on the machined surfaces of the castings was removed by electrolytic salt bath cleaning. [The electrolytic cleaning was similar to that described in Example 613.] The filler metal was BAg-1, and the flux was type 3A.

Three methods of heating for brazing were available: with gas burners, by induction, and in a salt bath. Heating with gas burners was too slow to be economical. Induction heating was satisfactory, but the production rate obtained with the available induction equipment was lower than with the available salt bath equipment. Therefore, the salt bath was selected.

The salt bath system included a semiautomatic conveyor (manually loaded and unloaded) that carried the assemblies through the bath, which was maintained at 1600 F, and through a subsequent water quench, which removed the salt. The time in the salt bath was such that the assembly did not reach bath temperature.

Fixtures were of type 304L stainless steel and were designed so that assemblies of various sizes could be accommodated. Additional conditions for salt bath brazing are given in the table that accompanies Fig. 3.

In the foregoing example, the salt bath was operated at 1600 F. This high temperature will severely reduce the strength of many cast irons. If this decrease in strength cannot be tolerated, either of two methods can be used for brazing in a salt bath: (*a*) employ a salt that can be used without excessive dragout at a temperature lower than 1600 F, or (*b*) develop a time cycle short enough that the temperature of the casting never exceeds about 1425 F.

In Example 614, the assemblies containing the malleable iron castings were water quenched to remove the brazing salt — a practice that is common with steel assemblies. However, to avoid warpage and cracking, brazed assemblies containing gray and ductile iron castings should never be water quenched from the brazing temperature. Instead, the assemblies should be cooled slowly to about 300 F and then immersed in water to remove the salt.

Brazing of Stainless Steel

*By the ASM Committee on Welding and Brazing of Stainless Steel**

ALL OF THE standard wrought stainless steels can be brazed satisfactorily, although their brazeability — in common with their weldability — varies with composition. In general, the more weldable stainless steels are also the more brazeable. Neverthless, the quality of brazed joints can often be improved by judicious selection of brazing process, brazing temperature, filler-metal composition, and protective atmosphere or activating flux, provided that such selection is compatible with performance in service.

Applicability. Brazing of stainless steels is most widely used for joining them to dissimilar metals, including stainless steels of dissimilar composition, carbon steels, low-alloy steels, copper alloys, and titanium. In fact, a principal advantage of brazing is that it can join a stainless steel to a variety of dissimilar metals to which it cannot be satisfactorily welded. Nine of the 17 examples in this article deal with the brazing of dissimilar-metal combinations (see Table 1). In addition, brazing makes it possible to select from a wide variety of brazing filler-metal compositions to achieve compatibility, strength, corrosion resistance and other desirable properties when dissimilar metals are to be joined.

When the most appropriate heating techniques are employed, brazing provides a method for obtaining strong, corrosion-resistant, leaktight joints in small or thin-wall components with a minimum of buckling or warpage. Brazing can produce joints in delicate assemblies that would be difficult or impossible to obtain with conventional welding processes. Brazing also lends itself to the mass production of small and medium-size assemblies on various types of continuous equipment. Finally, brazing makes possible the production of joints in inaccessible locations by the preplacement of filler metal and subsequent heating of the workpiece; often, such joints cannot be made by other joining processes.

Brazeability. As a class, stainless steels are more difficult to braze than are carbon and low-alloy steels. The difficulty is associated with the high chromium content of stainless steels, which accounts for the presence of chromium oxide films on the surface of all stainless steels. These oxides, which are refractory and strongly adherent, prevent wetting of the base metal by the molten filler metal.

The formation of chromium oxide is accelerated when stainless steels are heated in air. Therefore, although the oxide may have been removed from the surface by chemical cleaning at room temperature, a new oxide layer will form rapidly when the steel is heated in air to the brazing temperature and will seriously interfere with wetting. The adverse effect of oxides on wetting can be alleviated in any of four ways:

1 The steel can be chemically cleaned of surface oxide at room temperature, and shortly thereafter be heated to the brazing temperature in a chemically inert gaseous atmosphere, such as argon. This approach is seldom used, because the wetting action in inert gas is marginal.
2 The steel, after less intensive cleaning, can be heated directly to the brazing temperature in a strongly reducing atmosphere, such as dry hydrogen, which will chemically reduce the oxide and thereby promote wetting action.
3 The area at the joint can be coated with a chemically active flux that, during heating to the brazing temperature, will dissolve the oxide.
4 Heating and brazing can be done in a vacuum (after cleaning), thus preventing exposure to oxygen or water vapor and enabling effective wetting

Inclusions and Surface Contaminants. Base-metal inclusions and surface contaminants are even more deleterious in the brazing of stainless steel than they are in the brazing of carbon steel. Base-metal inclusions such as oxides, sulfides and nitrides interfere with the flow of filler metal. Flow is also impeded by surface contaminants, which may include lubricants such as oil, graphite, molybdenum disulfide, and lead, which are applied during machining, forming and grinding.

Some of the filler-metal powders (in paste form) used with stainless steel contain organic binders; acrylics and other plastics are often used for this purpose. Although some binders form a soot residue, this residue usually does not interfere with filler-metal flow.

The brazing characteristics of stainless steel can also be seriously impaired by unsuitable fixturing materials, such as graphite, or by a protective atmosphere with a nitriding potential. Carbon in graphite fixtures will unite with hydrogen to form methane (CH_4), which will carburize stainless steel and impair its corrosion resistance. Dissociated ammonia, unless sufficiently dry and completely (100%) dissociated, will nitride stainless steel. Both carburizing and nitriding will interfere with brazing quality.

Brazing Processes. Stainless steels can be brazed by all conventional brazing processes, including furnace, torch, induction, resistance and salt bath

*For committee list, see page 245. More than half the examples presented in this article were contributed by members of other Metals Handbook welding and brazing committees.

Table 1. Summary of Brazing Conditions Employed in Examples in This Article

Example	Name of assembly	Base metals brazed	Filler metal	Brazing temperature, F	Brazing atmosphere	Time at brazing temp, minutes

brazing. Furnace brazing is most widely used, because for most applications brazing in a prepared atmosphere or in a vacuum is required. The extensive use of furnace brazing is demonstrated by the fact that, out of the seventeen examples of brazing applications presented in this article (and summarized in Table 1), eleven are concerned with furnace brazing.

Filler Metals

Most stainless steels can be brazed with any one of several different filler metals, including silver alloys, nickel alloys, copper, and gold alloys. Copper alloy filler metals that contain phosphorus (the BCuP group) are never used for brazing steels, because of the brittle phosphides and intermetallics formed at the joint interface. In most applications, filler metals are selected for mechanical properties, corrosion resistance, and compatibility, rather than for brazeability.

Table 2 lists compositions, solidus and liquidus temperatures, and applicable brazing-temperature ranges of the filler metals most often used for the brazing of stainless steels. Table 1 lists the filler metals used in the 17 examples presented in this article.

Silver alloys (the BAg group) are the most widely used filler metals for brazing stainless steel. Alloy BAg-3, which contains 3% nickel, is probably the most widely used of the silver alloys, although several other silver alloys are also used and have proved successful (see Tables 1 and 2).

Silver brazed joints cannot be used for high-temperature service. Recommended maximum service temperature is 400 F. Recommended allowances on joint fit for silver brazing are relatively loose — generally, 0.002-in. to 0.004-in. diametral clearance.

Of the silver alloy filler metals shown in Table 2, all except BAg-19, and possibly BAg-13, are used at brazing temperatures that fall within the effective range of sensitizing temperatures (1000 to 1600 F) for austenitic stainless steels. It is in the sensitizing-temperature range that carbide precipitation occurs, resulting in impairment of the corrosion resistance of the base metal. Carbide precipitation, however, depends on time as well as on temperature, and exposure to the sensitizing-temperature range for only a few minutes is unlikely to result in a significant amount of precipitate. Nevertheless, the lower melting temperatures of the silver alloys prohibit re-solution treatment of the base metal after brazing, and if corrosion resistance in service is sufficiently critical, either an extra-low-carbon type or a columbium-tantalum-stabilized type should be selected instead of a nonstabilized austenitic steel.

Also, it should be noted that all of the silver alloy filler metals contain appreciable amounts of copper and zinc, singly or in combination. Overheating or heating for an excessive period of time may result in extensive penetration of grain boundaries by copper and zinc, thereby embrittling the brazed joint. Cadmium, which is added to some silver alloy filler metals to lower the melting temperature, will also penetrate grain boundaries. Cadmium-containing fumes are extremely toxic, and operators must take every precaution to avoid inhaling them. Cadmium fumes also will attack furnace parts and fixtures.

Zinc-containing and cadmium-containing silver alloy filler metals are not suitable for brazing components that

will be exposed to high vacuum in service. Selection of a suitable silver alloy filler metal for service in vacuum at pressures below 10^{-5} torr is considered in the following example.

Example 615. Selection of Filler Metal for a Type 304L Brazement Used in High Vacuum (Fig. 1)

The sleeve-and-tube assembly shown in Fig. 1 is typical of brazements used in vacuum systems. The tubes and the sleeve were of type 304L austenitic stainless steel.

Virtually all of the silver alloy filler metals are suitable for brazements used in vacuum chambers and pumps at pressures that are as low as 10^{-5} torr. However, for high-vacuum work (pressures of less than 10^{-6} torr), the filler metal must not contain cadmium or zinc. These metals will vaporize, interfering with the production of the vacuum and possibly contaminating the vacuum chamber and pumps. Consequently, filler metal BAg-18 (60% Ag, 10% Sn, rem Cu), which has proved satisfactory for brazing of assemblies used in high-vacuum applications, was used, with type 3B flux.

Brazing was done with a manually manipulated oxyacetylene torch, using a strongly reducing flame. The assembly shown in Fig. 1 could have been brazed in a furnace or by induction, but production was small and did not justify the investment for such equipment.

Ferritic and martensitic stainless steels that contain little or no nickel are susceptible to interface corrosion in plain water or in moist atmospheres when brazed with nickel-free silver alloy filler metals, using a liquid or paste flux. Filler metal containing nickel will help to prevent interface corrosion. However, for complete protection, special brazing alloys containing nickel and tin should be used and brazing should be done in a protective atmosphere without flux.

Nickel alloys (the BNi group) usually rank next to the silver alloys in frequency of use as brazing filler metals for stainless steels (see Table 1). Nickel alloy filler metals provide joints that have excellent corrosion resistance and high-temperature strength. However, they alloy with stainless steel and form phases that have two undesirable characteristics: (*a*) they are considerably less ductile than either the base metal or the filler metal, even at elevated temperatures, and thus are a potential source of rupture; and (*b*) the alloys formed with stainless steel are higher-melting alloys that are likely to freeze and block further flow into the joint during brazing. This does not usually cause difficulty in a shallow joint, for which zero clearance is generally recommended. However, to achieve flow in deep joints, diametral clearances of as much as 0.004 to 0.008 in. are necessary. Knurling of male members sometimes helps in centering loosely fitting components. With such large clearances, joints brazed with nickel alloy filler metals do not develop their greatest strength. With zero clearance, the braze metal contains less base metal and therefore is stronger.

Because of the relatively high brazing temperatures required for the nickel alloy filler metals (see Table 2), their use is generally restricted to furnace brazing in a reducing atmosphere, although there are occasional exceptions (see Fig. 16 and related text).

Type 304L; silver alloy filler metal (BAg-18)

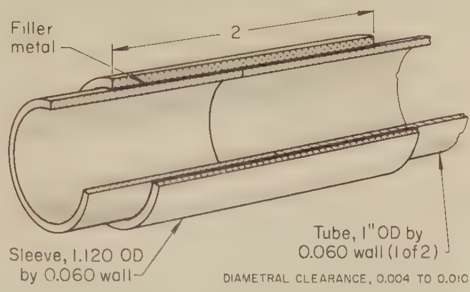

Fig. 1. Assembly that was torch brazed with a silver alloy filler metal containing no zinc or cadmium, because of use of the brazement in a high-vacuum system (Example 615)

Copper filler metals (the BCu group) melt at about 1980 F and flow freely at 2050 F. Copper is not recommended for exposure to certain corrosive substances, such as the sulfur in jet fuel and in sulfur-bearing atmospheres. When a copper filler metal is used, recommended diametral allowances on joint fit range from 0.004-in. clearance to 0.002-in. interference.

The high brazing temperature and the need for a protective atmosphere generally restrict the use of copper filler metal to furnace brazing.

Gold alloys (the BAu group) are sometimes used for brazing stainless steel. The high brazing temperatures required and the high cost of the gold alloys restrict the use of these filler metals to specialized applications (see Example 617). When a gold alloy is used, alloying with the stainless steel base metal is minimized and, as a result, joints exhibit good ductility.

Fluxes

For furnace brazing in strongly reducing or inert atmospheres, flux usually is not required. However, in some furnace brazing applications a flux is necessary (see Example 624). A flux is always required for torch brazing and is usually required for induction and resistance brazing, unless atmospheric protection is provided.

Either of two AWS types of flux (3A and 3B) is suitable for all stainless steel brazing applications where a flux is needed. Both types are available in powder, paste and liquid forms.

Type 3A flux contains boric acid, borates, fluorides, fluoborates and a wetting agent. Its effective temperature range is 1050 to 1600 F. It is suitable for use with silver alloy filler metals.

Type 3B flux contains the same ingredients as type 3A, but not in the same proportions, and has a higher effective temperature range (1350 to 2100 F). This type of flux is often selected for use with silver alloy filler metals if the brazing temperature is above 1350 F, and is well suited for use with copper (BCu), nickel alloy (BNi), and gold alloy (BAu) filler metals.

Furnace Atmospheres

Almost all furnace brazing of stainless steel is done in a protective gas or in vacuum. One exception is the application described in Example 626, in which air was the furnace atmosphere. In this application, a flux was used and the time at brazing temperature was short, which helped to prevent excessive oxidation.

The protective atmospheres most often used in furnace brazing of stainless steel are dry hydrogen and dissociated ammonia; both are effective in reducing oxides, protecting the base metal and promoting the flow of filler metal. The low-cost exothermic atmospheres that are widely used in furnace brazing of low-carbon steel are not suitable for stainless steel. An inert gas, such as argon, or vacuum may be used to satisfy special requirements and to provide protection in applications for which hydrogen or hydrogen-bearing gases are unsatisfactory.

Selection of furnace atmosphere depends on the degree of protection that must be given to the base metal or metals, the flow characteristics of the filler metal, the brazing temperature, and cost. Special requirements that arise from the brazing of dissimilar metals are often a major factor in atmosphere selection. Availability of equipment may also be of importance. Ten of the eleven examples of furnace brazing that are presented in this article involve the use of protective atmospheres, including dry hydrogen, dissociated ammonia, and argon.

Furnace Brazing in Dry Hydrogen

A dry hydrogen atmosphere is preferred for many applications of brazing stainless steel, and was used in seven of the 11 examples in this article that deal with furnace brazing. Hydrogen, the most strongly reducing of protective atmospheres, reduces chromium oxide and provides for excellent wetting by some filler metals without the need for flux. The principal disadvantages of hydrogen are its high cost, the difficulty in getting it sufficiently dry, the need for special furnace equipment, and the danger involved in storing and handling hydrogen.

Examples of Practice. The first six of the seven examples that follow describe applications in which a specific type of stainless steel was joined to the same type or to another stainless steel. (The sixth of these examples describes an application in which changing from gas tungsten-arc welding to furnace brazing decreased cost and increased production rate.) The seventh example describes brazing of stainless steels to a low-carbon low-alloy steel.

Example 616. Selection of BAg-13 Silver Alloy Filler Metal for Brazing at 1700 F (Fig. 2)

The type 347 stainless steel retainer assembly shown in Fig. 2 was furnace brazed in dry hydrogen, using BAg-13 silver alloy filler metal. This filler metal was selected in preference to lower-melting silver alloys because the upper limit of the brazing-temperature range of BAg-13 (1575 to 1775 F) permitted brazing at 1700 F. At furnace temperatures above 1600 F, dry hydrogen is strongly reducing, and the use of a brazing flux is not required for satisfactory wetting action. Thus, by judicious selection of filler metal and furnace atmosphere, the extra costs of applying a flux, and of removing flux residue after brazing, were avoided.

The components were vapor degreased, assembled with outside diameters concentric, and (to make them self-jigging) were spot welded at four locations, 90° apart (see Fig. 2). A ring of 0.040-in.-diam filler-metal wire was preplaced at the joint, and assemblies were loaded two-across on the mesh belt of a conveyor-type furnace. The heating chamber of the furnace was elevated from the entrance and discharge level to conserve the lighter-than-air hydrogen. Production rate and additional processing details are given in the table with Fig. 2.

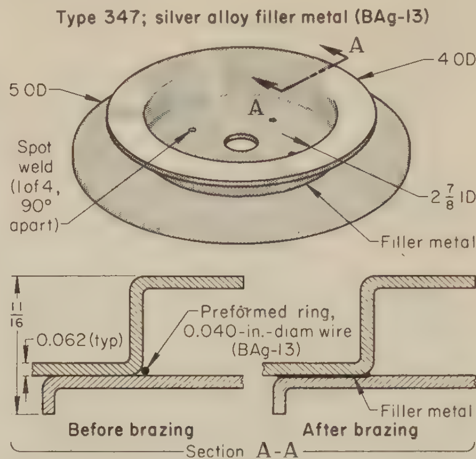
Quality standards for brazed assemblies, which were checked by 100% visual inspection, required that the joint exhibit full braze penetration (360° fillets on both sides of the joint) and be pressure-tight.

Example 617. Use of a Gold Alloy Filler Metal for Brazing of 5104 Joints in an Aerospace Heat Exchanger (Fig. 3)

In the fabrication of a high-reliability heat exchanger for manned space flights, 2552 type 347 stainless steel fins 0.004 in. thick were brazed to 0.025-in.-thick type 347 stainless steel side panels, as shown in Fig. 3. The 5104 fin-to-panel joints had to be strong and corrosion resistant.

Silver alloy and copper brazing filler metals could not be used because of incompatibility with sulfur-bearing rocket fuel. The BNi series of nickel alloys had the necessary compatibility, but made brittle joints that were unreliable under tension peel stress. Therefore, gold alloy filler metals were considered. The necessary brazing characteristics for the fin-to-panel joints were found in BAu-4 (81.5% gold, remainder nickel). The strength and toughness of the brazed joints made with this alloy justified its high cost.

The fins and side panels were cleaned by vapor degreasing. The side panels were pickled, rinsed in clean water and dried. The filler metal was coated on the panels in the form of a powder suspended in an organic binder. Multiple lap joints were made between the flat-crown-hairpin ends of the fins and the flat side panels. The assembly was placed in a fixture (see Fig. 3), and the entire assembly and fixture were placed in the retort of a bell-type furnace and sealed. The sealed retort was purged with a volume of hydrogen equivalent to five times that of the retort. The retort was then heated to the brazing temperature of 1860 F and held for 7 to 10 min. Joint gap at brazing temperature was 0.000 to 0.010 in. Then the retort was purged with argon while being cooled to 300 F, and was not opened until after purging and cooling.



Furnace Brazing in Dry Hydrogen

Furnace	Continuous conveyor(a)
Fixtures	None
Furnace temperature	1800 ± 10 F
Brazing temperature	1700 ± 10 F
Hydrogen dew points	—100 F (incoming); —70 F (exhaust)
Hydrogen flow rate	400 cu ft per hour
Filler metal	BAg-13, 0.040-in.-diam wire(b)
Joint position during brazing	Horizontal
Conveyor travel speed	30 ft per hour
Time at brazing temperature	5 min(c)
Production rate	120 assemblies per hour

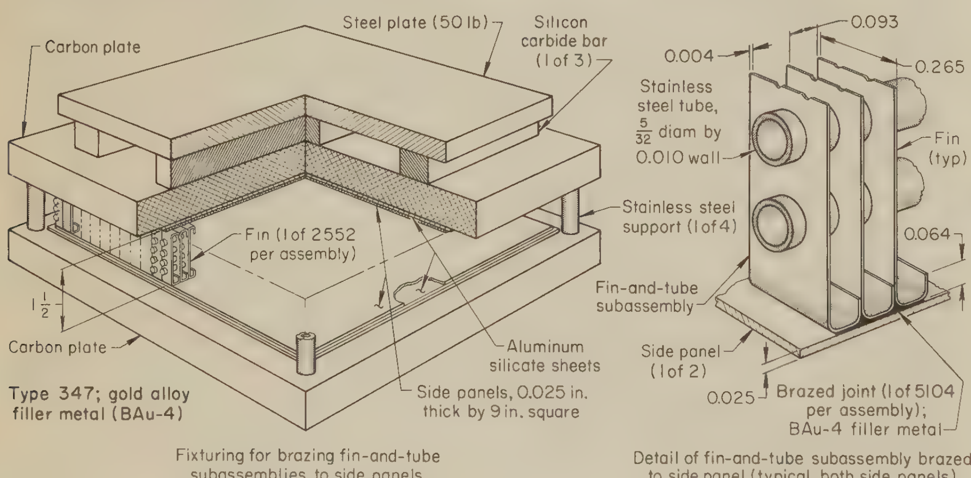
Fig. 2. Retainer assembly that was furnace brazed at 1700 F, using BAg-13 filler metal (Example 616)

The joints brazed by the above procedure were the final brazed joints in the assembly. In a prior brazing operation, tubes had been joined to the fins (see Fig. 3) by brazing at 1970 F using a higher-melting gold alloy filler metal composed of 70% gold, 22% nickel and 8% palladium.

Completed assemblies were visually inspected and pressure tested at pressures that far exceeded the pressures to be encountered in service. Typical service pressures were 270 psi on the outside of the tubes and 1710 psi on the inside. Acceptance pressure tests were at 540 psi on the outside of the tubes and 2275 psi on the inside. Selected brazed assemblies were tested to bursting. These samples were required to withstand at least three times the service pressures before bursting. The assemblies brazed with gold alloy filler metals passed all tests and had three times the bursting strength of assemblies brazed with nickel alloys. Additional brazing conditions are given in the table with Fig. 3.



Furnace Brazing in Dry Hydrogen

(c) 200-mesh powder suspended in an organic binder. (d) Including cooling to 300 F in retort, which was purged with argon before being opened.

Fig. 3. Heat-exchanger assembly, in brazing fixture, and detail of joints between 2552 fins and two side panels, which were brazed with gold alloy filler metal to obtain required strength (Example 617)

Example 618. Combination Brazing and Solution Heat Treatment of an Assembly of Three Types of Stainless Steel (Fig. 4)

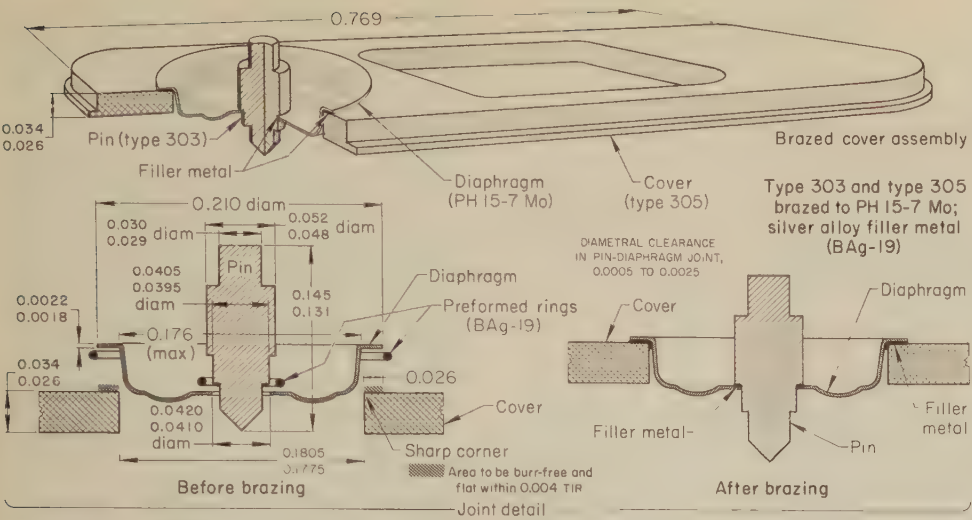
Three different stainless steels were selected to make the cover for a hermetically sealed switch. The switching action had to be transmitted through the cover without breaking the seal. This was accomplished by providing a diaphragm through which a shouldered pin was inserted, as shown in Fig. 4. The switch was actuated by depressing the pin, which, in turn, deflected the diaphragm. The pin, of type 303, the diaphragm, of PH 15-7 Mo, and the cover, of type 305, were assembled as shown in Fig. 4 and furnace silver brazed in dry hydrogen.

Silver alloy filler metal BAg-19 was chosen, because it flowed at a temperature that coincided with the solution heat treating temperature for the PH 15-7 Mo diaphragm (1750 F). A holding fixture was needed to keep the PH 15-7 Mo diaphragm in position during the brazing cycle; to avoid carburizing the diaphragm, the material selected for the fixture was stainless steel, rather than graphite. The furnace was a batch-type tube furnace with a 5-in.-diam high-heat zone 18 in. long. Moisture content of the hydrogen atmosphere was carefully controlled, because with too dry an atmosphere, the lithium-containing filler metal flowed too freely and did not seal the joints.

After being cleaned, the components were assembled with two preformed rings of BAg-19 wire; tweezers were used to avoid contamination of the cleaned surfaces. Each assembly was held in a stainless steel fixture, which in turn was placed on a stainless steel furnace sled. The sled was pushed into the high-heat zone of the furnace and held at 1750 F for 10 min, pulled into an intermediate cooling zone at 1000 F and held for 5 min, and finally pulled to the water-cooled zone, where it cooled to room temperature. Brazing of the two joints and solution treating of the PH 15-7 Mo diaphragm were accomplished simultaneously at the brazing temperature (1750 F). To complete the heat treating process, the assembly was cooled to —100 F, held for 8 hr, and then aged at 950 F for 1 hr.

A 1-in.-square piece of PH 15-7 Mo was processed with each batch of cover assemblies, and was used as a hardness-test specimen to verify that the diaphragms had been correctly heat treated. Brazed assemblies were inspected by the brazing operator. It was required that the joints be fully sealed and have no voids, and that the pins be perpendicular within 4°. Perpendicularity was measured on a comparator. Randomly selected samples were given a push-out test, in which joints had to withstand a push of 14 lb. All assemblies were given 100% visual inspection at a magnification of 13 diameters.

Additional brazing conditions are given in the table with Fig. 4.



Conditions for Furnace Brazing in Dry Hydrogen

Furnace	Batch-type tube(a)	Time at brazing temperature	10 min
Fixture material	Stainless steel(b)	Time in first cooling zone (1000 F)	5 min
Brazing temperature	1750 ± 15 F	Time in final cooling zone(d)	5 min
Filler metal	BAg-19 wire(c)	Production in 8 hr	1000 assemblies

(a) Three-zone furnace, with a high-heat zone 5 in. in diameter by 18 in. long. (b) Fixture located and held components of assembly together, and was placed on a stainless steel sled for transport through the furnace. (c) Preformed rings. (d) Water-cooled zone, in which assembly was cooled to room temperature. Then, to complete heat treatment of the PH 15-7 Mo diaphragm, assembly was cooled to −100 F and held for 8 hr, then aged at 950 F for 1 hr.

Fig. 4. Three-steel switch-cover assembly for which time at brazing temperature was also part of solution heat treatment of the PH 15-7 Mo diaphragm (Example 618)

Example 619. Simultaneous Brazing of 370 Joints in a Heat-Exchanger Assembly (Fig. 5)

An air-to-air heat-exchanger assembly, shown in Fig. 5, consisted of 185 thin-wall (0.008-in.) tubes and two 1/16-in.-thick headers. All components were made of type 347 stainless steel. The tubes were assembled with the headers by flaring the tube ends to lock them in place and provide metal-to-metal contact for brazing filler metal. All 370 joints were brazed during a single pass through a continuous conveyor-type electric furnace.

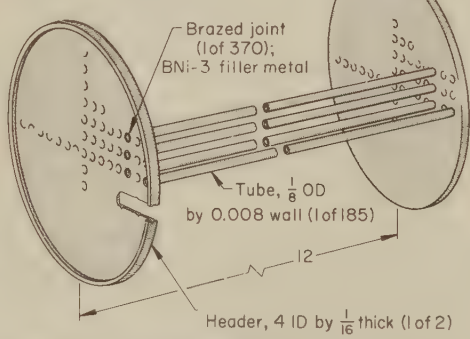
Although a nickel alloy filler metal was preferred for this high-temperature application, because of the resistance to heat and corrosion that nickel alloys provide, selection among the nickel alloys presented a problem. Higher-melting, boron-containing nickel filler metals, such as BNi-1 and BNi-3, alloy with the base metal and therefore are likely to erode thin materials. Fortunately, the extent of erosion can be modified by control of the brazing temperature and time, and the amount of filler metal.

Although there are nickel filler-metal alloys that contain silicon in place of boron, these alloys generally require much higher brazing temperatures, which can result in grain coarsening in the base metal. Therefore, after numerous tests, BNi-3 filler metal was selected on the basis of brazing temperature and excellent fluidity, and the problem of applying the correct amount of filler metal to avoid erosion was solved by preparing a slurry from an accurately controlled mixture of filler-metal powder, acrylic-resin binder, and xylene thinner.

Before the filler metal was applied, the heat-exchanger assembly was cleaned ultrasonically in acetone, and was carefully weighed to determine the proportionate weight of filler metal required. One-half the total amount of filler metal was then applied to one end of the assembly by spraying. The assembly was then reweighed, and the remainder of the filler metal was applied to the opposite end. At all stages of processing, the assembly was handled by operators wearing clean lint-free white cotton gloves.

The assembly was placed on a holding fixture made of stainless steel sheet, to which a stop-off compound had been applied to prevent the assembly from brazing to the fixture if the brazing filler metal flowed excessively. Assemblies were placed 12 in. apart on the conveyor belt as they traveled through the furnace at 30 ft per hour under protection of dry hydrogen. Additional furnace details and brazing conditions are given in the table with Fig. 5.

Type 347; nickel alloy filler metal (BNi-3)



Furnace Brazing in Dry Hydrogen

Furnace	Continuous conveyor(a)
Fixture material	Type 347 stainless steel(b)
Furnace temperature	2050 ± 10 F
Brazing temperature	1950 ± 10 F
Hydrogen dew points	−100 F (incoming); −70 F (exhaust)
Hydrogen flow rate	600 cu ft per hour
Filler metal	BNi-3 powder(c)
Conveyor travel speed	30 ft per hour
Time at brazing temperature	5 min
Cooling	In hydrogen atmosphere
Production rate	15 assemblies per hour

(a) Electrically heated (60 kw), constructed with heating chamber (6 in. high, 12 in. wide, 36 in. long) higher than entrance and discharge ends. (b) Holding fixture fabricated from 1/8-in.-thick sheet. (c) Mixed to a slurry with acrylic resin and xylene thinner; powder-to-vehicle ratio, 70 to 30.

Fig. 5. Heat-exchanger assembly with 370 tube-to-header joints that were brazed in one pass through a furnace (Example 619)

After brazing, both sides of each joint were subjected to 100% visual inspection for the presence of fillets; assemblies were pressure tested in accordance with customer requirements.

Because of the thin-wall (0.008-in.) tubing, brazing this assembly provided more consistent results than could have been achieved by gas tungsten-arc welding. In addition, the cost of welding 370 joints would have been many times the cost of furnace brazing.

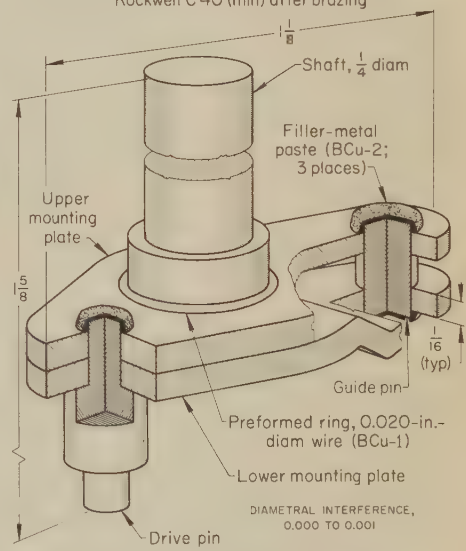
Examples 620 and 621. Combining Brazing and Hardening of Assemblies Made of Type 410 Stainless Steel

Example 620 — Shaft Assembly (Fig. 6). The shaft assembly shown in Fig. 6 consisted of three bar machine products (a shaft, a drive pin and a guide pin) and two stampings (upper and lower mounting plates), all made from type 410 stainless steel, that were furnace brazed together with four joints. By brazing with copper filler metal at 2050 F, it was possible to austenitize and harden the assembly to the required minimum hardness of Rockwell C 40 during the brazing and cooling operations, thereby avoiding a separate hardening operation after brazing.

Because the joints were all relatively short, an interference fit of 0.000 to 0.001 in. was satisfactory. (Normally, with longer joints in stainless steel, a clearance fit between mating parts is required.) Automatic staking of components was used to make the assembly self-fixturing.

As shown in Fig. 6, a full ring of 0.020-in.-diam BCu-1 copper wire was preplaced

Type 410; copper filler metals (BCu-1 wire, BCu-2 paste); Rockwell C 40 (min) after brazing



Furnace Brazing in Dry Hydrogen

Furnace	Continuous conveyor(a)
Fixtures	None(b)
Furnace temperature	2150 ± 10 F
Brazing temperature	2050 ± 10 F
Hydrogen dew points	−100 F (incoming); −70 F (exhaust)
Hydrogen flow rate	400 cu ft per hour
Filler metal	BCu-1 wire, BCu-2 paste(c)
Conveyor travel speed	20 ft per hour
Time at brazing temperature	8 min(d)
Cooling	In hydrogen atmosphere
Production rate	800 assemblies per hour

(a) Electrically heated (60 kw), constructed with heating chamber (6 in. high, 12 in. wide, 36 in. long) higher than entrance and discharge ends. (b) Components were staked, for self-fixturing. Assemblies, supported by ceramic spacers to keep shaft end up, were brazed on trays. (c) 0.020-in.-diam wire in a preformed ring; paste was applied at one end of drive pin, both ends of guide pin. (d) Assemblies were in high-heat zone for about 10 min.

Fig. 6. Four-joint shaft assembly that was simultaneously furnace brazed and heated for hardening (Example 620)

around the ¼-in.-diam shaft to braze the shaft to the upper and lower mounting plates, and a small amount of BCu-2 copper paste was applied at one end of the drive pin to braze it to the two mounting plates. Because of the separation between the two plates on the guide-pin side, a small amount of BCu-2 copper paste was placed on each end of the guide pin. The copper paste was applied manually. The assemblies were placed in brazing trays, with the shaft in a vertical position, and were supported in this position by ceramic spacers.

The brazing trays were placed on the mesh belt of a continuous conveyor furnace containing a dry hydrogen atmosphere and were transported up an incline to the horizontal preheat and high-heat chambers at a speed of 20 ft per hour. Because the assemblies were small, they heated to brazing temperature in about 2 min. After 8 min at brazing temperature, the assemblies were conveyed into water-jacketed cooling chambers, where they cooled rapidly in the hydrogen atmosphere to room temperature. Brazed assemblies emerged from the exit end of the furnace bright and free of oxidation.

The brazed assemblies were visually inspected 100% for complete joint coverage. Hardness tests on a sampling basis were used to determine whether the assemblies had responded properly to hardening. Tempering to the desired final hardness followed the simultaneous brazing and hardening operation. Additional brazing conditions are given in the table with Fig. 6.

Example 621 — Impeller Assembly: Furnace Brazing vs Gas Tungsten-Arc Welding (Fig. 7). The impeller shown in Fig. 7 is typical of those used in food-processing and pharmaceutical-processing equipment. Originally, the type 410 stainless steel vanes and disk were joined by gas tungsten-arc welding. Because type 410 is an air-hardening steel, preheating and postheating were required, to prevent cracking. In addition, the assembly required reheat treatment after welding, to obtain a hardness of Rockwell C 32 to 38. The following processing steps were required when gas tungsten-arc welding was used:

1 Degrease and clean.
2 Assemble vanes in disk.
3 Preheat assembly in oven to 450 F.
4 Weld (maintaining an interpass temperature of 400 to 450 F).
5 Postheat at 600 F for 2 hr.
6 Bright harden.
7 Temper to Rockwell C 32 to 38.

In 500-assembly lots, the cost of these operations to the manufacturer was approximately $3.75 per assembly, and the production rate was low.

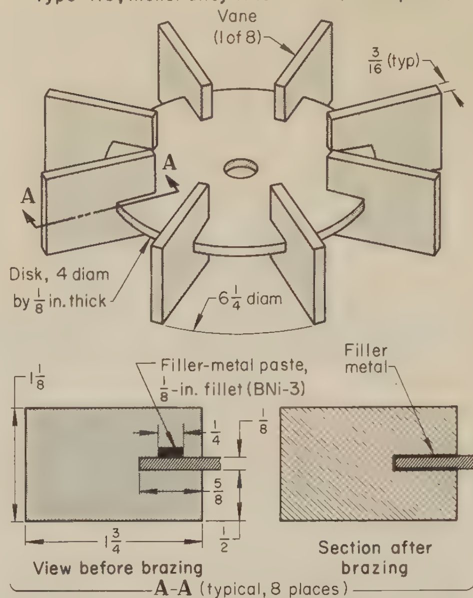
A change to furnace brazing reduced cost to $0.95 per assembly, increased the production rate, and also eliminated the need for a separate hardening operation. The sequence of steps for combined furnace brazing and hardening was:

1 Degrease and clean.
2 Assemble vanes in disk.
3 Apply BNi-3 filler-metal paste to one area of each joint.
4 Braze and harden in the same operation.
5 Temper to Rockwell C 32 to 38.

After the components had been vapor degreased, the vanes were assembled in the disk, using an assembly fixture and a small hand-operated arbor press (a light interference fit made the assembly self-jigging). Then a ⅛-in. fillet of filler-metal paste was applied by air applicator to a ¼-in.-long area on each vane where the vane and disk intersected (see section A-A in Fig. 7).

Assemblies were loaded on a 12-in.-wide continuous mesh belt and conveyed into the furnace, where they were brazed and austenitized at 2000 F, under protection of dry hydrogen. The assemblies emerged from the cooling chamber bright and clean, fully hardened, and with completely uniform brazed joints between all vanes and the disk. Assemblies were then ready for tempering. Inspection was 100% visual. Additional brazing conditions are given in the table with Fig. 7.

Type 410; nickel alloy filler metal (BNi-3 paste)



Furnace Brazing in Dry Hydrogen

Furnace	Continuous conveyor(a)
Furnace temperature	2100 ± 10 F
Brazing temperature	2000 ± 10 F
Hydrogen dew points	—100 F (incoming); —70 F (exhaust)
Hydrogen flow rate	400 cu ft per hour
Filler metal	BNi-3 paste(b)
Time at brazing temperature	5 min
Cooling	In hydrogen atmosphere
Production rate	120 assemblies per hour

(a) Electrically heated (60 kw), constructed with heating chamber (6 in. high, 12 in. wide, 36 in. long) higher than entrance and exit ends. (b) Paste consisted of 80% BNi-3 powder and 20% acrylic resin with acetone thinner.

Changing to furnace brazing from gas tungsten-arc welding decreased cost per assembly by about 75%, increased production rate, and eliminated the separate hardening operation.

Fig. 7. Impeller that was simultaneously furnace brazed and hardened (Example 621)

The cost of producing similar impeller assemblies from type 321, an austenitic grade of stainless steel, by furnace brazing in dry hydrogen and by gas tungsten-arc welding was as follows:

Furnace brazing	$0.91 each
Gas tungsten-arc welding	$3.15

In almost any joining application involving small parts, the advantage of brazing over welding is likely to increase as the number of joints increases. For instance, in this application, if the number of vanes per impeller were doubled, the advantage of brazing would increase proportionately.

Example 622. Brazing Stainless Steels to a 12.5% Cr Turbine-Quality Steel (Fig. 8)

The assembly shown in Fig. 8 is typical of the design of impellers used in turbo-compressors. The function of the impeller was to raise the pressure and temperature of the gas passing through the compressor. Impeller speeds ranged from 3000 to 30,000 rpm. The stainless steel impeller blades were used instead of aluminum alloy blades where the working temperature was unusually high, or where the gases passing through the compressor were especially erosive or corrosive.

Brazed impellers were preferred to cast impellers because the cast product entailed extremely high pattern costs, could not be salvaged when defective, and resulted in a rejection rate that was 75% above that of the brazed impeller.

The brazed impellers were made by copper brazing 20 curved blades of type 403 stainless steel to a cover plate, and to a hub plate and type 304 blade-locating pins that were inserted in the hub plate and were also brazed to it. The locating pins were made of wire that was sheared to desired length in a special fixture, and then cleaned by washing in acetone. The hub plate and cover plate were made of a turbine-quality stainless forging steel of the following composition: 0.06 to 0.13 C, 0.25 to 0.80 Mn, 12.0 to 13.0 Cr, 0.50 max Si, 0.03 max P, 0.03 max S, and 0.50 max Ni.

Blades were made from a formed cylinder, the seam of which was welded by the shielded metal-arc process using an E308-16 electrode. The welded cylinder was then stress relieved at 1300 to 1350 F for 1½ hr per inch of section and cooled in still air. The cylinder was then rough and finish machined and the blade sections were sawed out and finish machined. Width of the blades was held within 0.001 in. TIR in a set. Each blade was then drilled in two places to accommodate locating pins. The hub plate and cover plate were rough and finish machined to a finish of 125 micro-in. on the brazing surfaces and held to a flatness within 0.001 in. Top and bottom brazing strips (filler-metal preforms) were stamped from oxygen-free copper strip (99.95% Cu; equivalent to BCu-1), cold rolled to the half-hard temper. The top brazing strip had four integral tabs that, when bent, held it on the blade (see detail A and section B-B, Fig. 8).

Before assembly, the hub plate, cover plate, blades, and brazing strips were vapor degreased with a spray of trichlorethylene. Then the brazing surfaces of the hub plate, cover plate and blades were grit blasted with SAE G18 steel grit, after which these components were again vapor degreased in trichlorethylene. Finally, all components, including the brazing strips, were cleaned with acetone.

Assembly, brazing and heat treatment were done in the following sequences:

Assembly

1 Six ceramic blocks were placed in the bottom half of a type 304 box-type retort (Fig. 8) and arranged to provide the hub plate with uniform support above the bottom of the retort.
2 The hub plate was positioned on the ceramic blocks.
3 Forty blade-locating pins (two per blade) were inserted in pilot holes in the hub plate.
4 Bottom copper brazing strips were placed over the locating pins.
5 Blades were positioned over bottom brazing strips on locating pins.
6 Top copper brazing strips were placed on the blades and secured by bending tabs on the strips down on blade foils (detail A and section B-B in Fig. 8).
7 The cover plate was set into position, and held by means of locating clamps.
8 Two thermocouples were threaded through the thermocouple conduit in the bottom half of the retort (see Fig. 8), and welded to the cover plate at diametrically opposite locations corresponding to the front and back of the furnace. Thermocouples were made by threading one bare Chromel wire and one bare Alumel wire through oval, double-hole ceramic insulator sleeves. The work end of each thermocouple wire was welded to form a terminal bead, using the gas tungsten-arc process. Extreme care was taken to avoid pickup of foreign metal when forming the bead.
9 The retort cover was placed in position, and the flanges of the cover and bottom half of the retort were seal welded.
10 A soap-bubble test for leakage was applied to the seal weld, using argon pressure.

Brazing

1 The retort was purged for 5 min with high-purity argon at 75 cu ft per hour.
2 The argon was shut off and hydrogen was turned on. Hydrogen was circulated through the retort at 75 ± 5 cu ft per hour until the gas leaving the retort had a dew point of —75 F or lower. Hydrogen was circulated at this rate throughout brazing.
3 The retort was placed in a preheated furnace (1150 ± 50 F).
4 Impeller temperature was brought to 1150 ± 50 F and held for 30 min.
5 Impeller temperature was raised to 2050 to 2075 F and held for 25 min.
6 Furnace was turned off, and cooled with a blower until impeller temperature reached 1700 F.

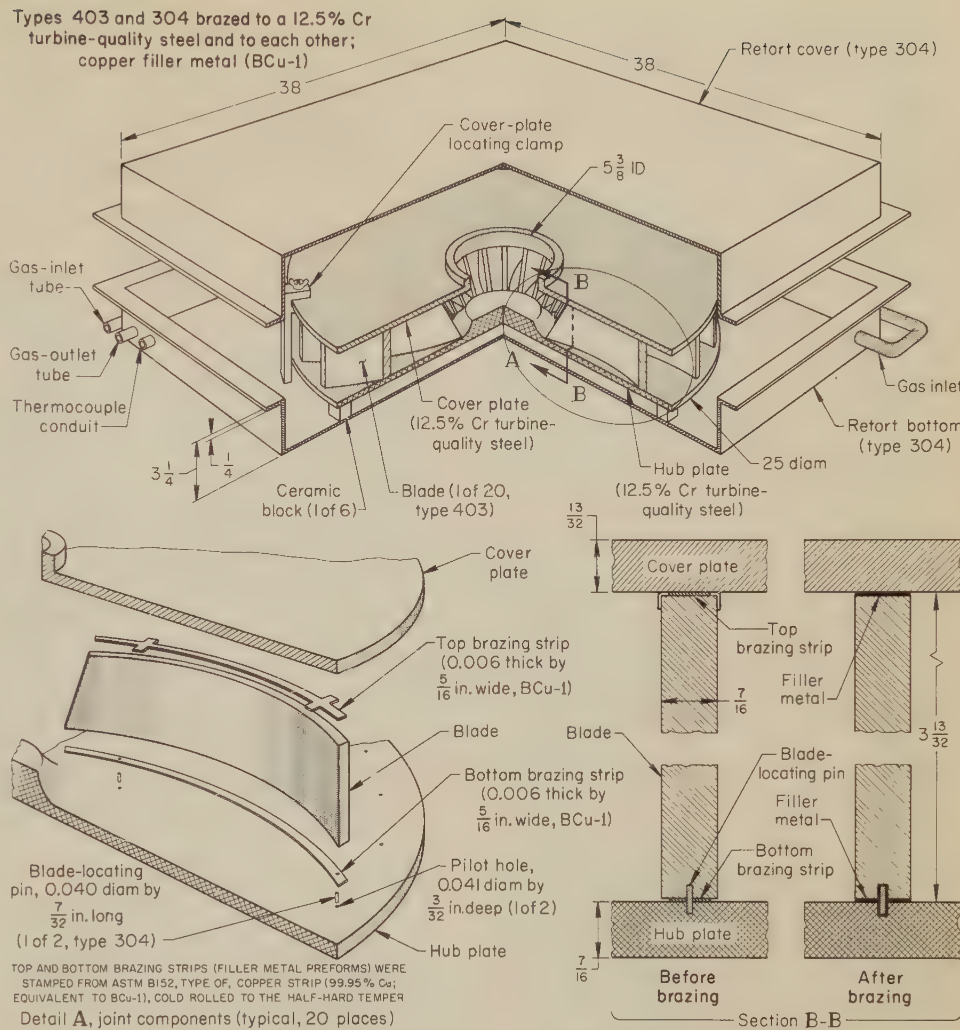
7 Furnace door was opened, and impeller was cooled to 1100 F.
8 Retort was removed from furnace, and impeller was cooled to 300 F.
9 Hydrogen being fed to retort was shut off, and retort was purged for 5 min with argon at 75 ± 5 cu ft per hour.
10 Retort was opened by grinding away the seal weld, and the impeller was removed.
11 Impeller was visually inspected to check braze quality; no visible voids or cracks were allowed.

Heat Treatment

1 Impeller was heated in inert atmosphere at 1775 to 1800 F for 1 hr.
2 Impeller was cooled in inert atmosphere to 200 F.
3 Impeller was reheated (tempered) at 1100 F (air atmosphere) for 1 hr, and then cooled in still air.

Braze quality was controlled by visual examination and dye-penetrant inspection; no voids or cracks in brazed joints were permitted. Hardness was also checked, and each impeller was subjected to a 2-min test run at 20% above the rated speed.

Additional brazing conditions are given in the table with Fig. 8.



Conditions for Furnace Brazing in Dry Hydrogen

Furnace	Box, gas fired	Hydrogen flow rate	75 ± 5 cfh(c)
Fixtures	Blade-locating pins(a)	Preheat in furnace	1150 ± 50 F for 30 min
Furnace temperature	2200 F max	Brazing temperature	2050 to 2075 F
Filler metal	BCu-1 brazing strips	Time at brazing temperature	25 min
Purging gas	Argon at 75 ± 5 cfh(b)	Postbraze heat treatment	(d)
Hydrogen dew points	—90 F (incoming); —75 F (exhaust)	Cleaning and brazing time	10.8 hr
		Heat treatment time	13 hr

(a) Pins, of type 304 stainless steel, were brazed to hub plate and blades as shown in illustration. (b) Sealed retort was purged with argon for 5 min. Argon was of 99.99% purity, with less than 0.0005% oxygen and less than 0.0002% nitrogen. Dew point was —76 F or lower. (c) Hydrogen was of 99.92% purity, with less than 0.0005% oxygen and with 0.07% max nitrogen. (d) In an inert atmosphere, assembly was heated at 1775 to 1800 F, held for 1 hr and cooled to 200 F. Then it was reheated in air to 1100 F and held for 1 hr.

Fig. 8. Impeller assembly in retort prior to furnace brazing, detail showing joint components, and section through a joint before and after brazing (Example 622)

Furnace Brazing in Dissociated Ammonia

Dissociated ammonia, when it is free of moisture and 100% dissociated, is a suitable atmosphere for brazing stainless steel with some filler metals without need for a flux. Dissociated ammonia is strongly reducing, but is less reducing than pure dry hydrogen. Consequently, although it will promote wetting action by reducing chromium oxide on the surface of stainless steel, it may not be sufficiently reducing to promote the flow of some filler metals, such as copper oxide powders. Because of its high (75%) hydrogen content, dissociated ammonia forms explosive mixtures with air and must be handled with the same precautions as those required for the handling of hydrogen.

A dissociated-ammonia atmosphere is prepared by heating anhydrous liquid ammonia in the presence of an iron or nickel catalyst. The decomposition of ammonia to form hydrogen and nitrogen begins at 600 F, and the rate of decomposition increases with temperature. Unless the atmosphere used in brazing stainless steel is completely decomposed (100% dissociated), even minute amounts of raw ammonia (NH_3) in the atmosphere will nitride stainless steel, especially the steels containing little or no nickel. In addition, because of the solubility of ammonia in water, the atmosphere coming from the dissociator must be extremely dry (preferably having a dew point of —80 F or lower). To ensure a very low dew point, the atmosphere coming from the dissociator is commonly processed in a molecular-sieve drier. To avoid oxidation of base metal and filler metal, the atmosphere must be kept pure and dry while it is inside the furnace.

Examples of Practice. In the two examples of production practice that follow, dissociated ammonia was used successfully in the furnace brazing of ferritic, austenitic and precipitation-hardening stainless steels.

Example 623. Brazing With BAg-19 Filler Metal in Dissociated Ammonia Without Flux (Fig. 9)

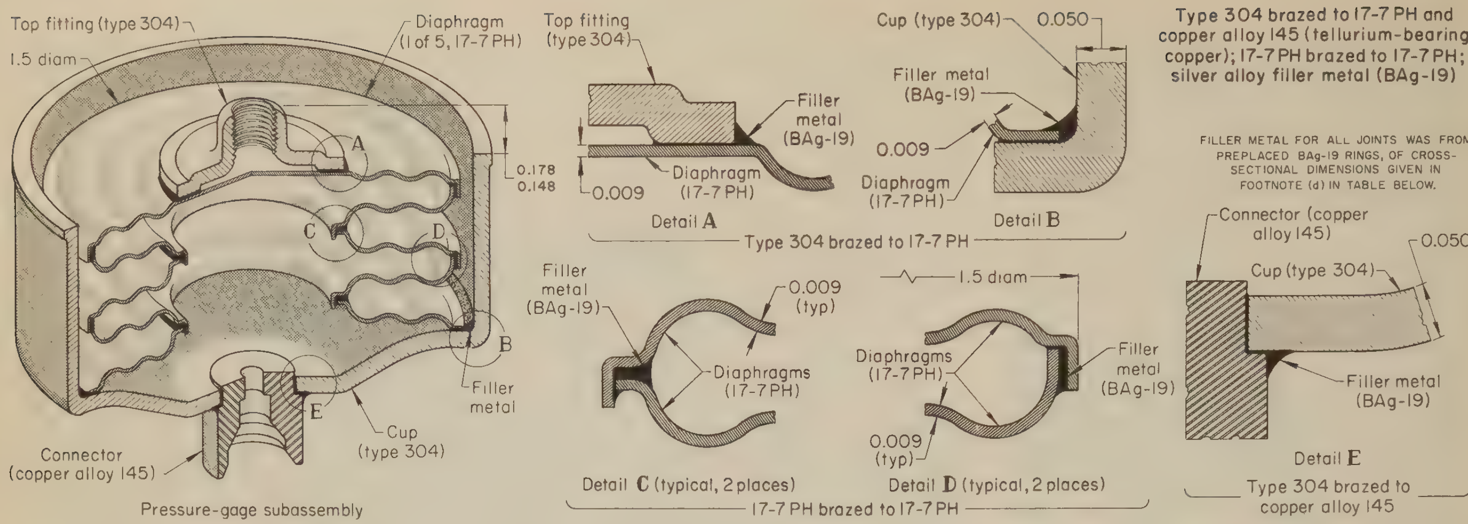
The pressure-gage subassembly shown in Fig. 9 was composed of five diaphragms of 17-7 PH stainless steel, a deep drawn cup and a top fitting of type 304 stainless steel, and a connector of copper alloy 145 (tellurium-bearing copper). Originally, these subassemblies were furnace brazed with a silver alloy filler metal that required a flux, and applying flux and assembling the fluxed components with gloved hands was time consuming. It was therefore decided to change to fluxless brazing in an atmosphere of dissociated ammonia; although this necessitated using a more expensive filler metal (BAg-19), its higher cost was offset by the greater productivity of each operator. In addition, subassemblies brazed with BAg-19 in dissociated ammonia exhibited fewer leaks and had improved corrosion resistance and better appearance than those brazed with the original filler metal and with flux.

Prior to brazing, the deep drawn type 304 cups were fully annealed at 2000 F. Annealing served to avoid erosive penetration of filler metal in zones of high residual stress. All components were chemically cleaned and then were assembled by hand, together with seven preplaced rings of filler metal. The assemblies were placed in holding fixtures, and the fixtures were loaded on the belt of a conveyor furnace heated to 1800 F. The cooling chamber of the furnace was cooled to below 60 F to ensure rapid cooling of the 17-7 PH diaphragms from the solution treating temperature, and thereby to combine solution treating with the brazing operation.

After brazing, the assemblies were cooled to —40 F, dried, and then heated to 950 F in dry dissociated ammonia to harden the diaphragms to Rockwell C 44 to 48.

Brazed assemblies were pressure tested in a bellows halogen leak detector by applying Freon at 75 psi and adding compressed air to bring the total pressure up to 300 psi. Leakage of Freon in the gas-air mixture would have been detected by the halogen leak detector. It was required that there be no leakage at the most sensitive setting of the leak detector.

The rejection rate for leakage, based on 750,000 bellows produced, dropped from



Conditions for Furnace Brazing in Dissociated Ammonia

Furnace ....Chain-belt conveyor(a)	Filler metal ....BAg-19, preplaced rings(d)	Heating time ....5 min
Furnace temperature(b) ....1800 F	Flux ....None(e)	Cooling-chamber temperature ....60 F max(f)
Dissociated-ammonia dew point ....—80 F(c)	Furnace belt speed ....10 in. per min	Precipitation-hardening temperature ..950 F(g)

(a) Electrically heated, with elevated high-heat zone. (b) For brazing the subassembly, and simultaneously solution heat treating the 17-7 PH diaphragms. (c) Achieved by running the dissociated ammonia through a molecular-sieve drier after cracking.

(d) Cross-sectional dimensions (and product forms) of filler-metal rings were as follows: for joint between diaphragm and top fitting (detail A), 0.050 in. wide by 0.004 to 0.005 in. thick (stamping); for outside joints between diaphragm segments (detail D) and joint between diaphragm and cup (detail B), 0.040 in. wide by 0.004 to 0.005 in. thick (ribbon); for inside joints between diaphragm segments (detail C), 0.030 in. wide by 0.005 in. thick (ribbon); and for joint between cup and connector (detail E), 0.060 by 0.010 in. (wire). (e) Use of BAg-19 eliminated the need for flux, which had been required with the silver alloy filler metal originally used.

(f) To cool rapidly from 1800 F and ensure solution treatment of the 17-7 PH diaphragms. (g) In dry dissociated ammonia, after subassembly had been cooled to —40 F and dried. The 17-7 PH diaphragms were hardened to Rockwell C 44 to 48.

Fig. 9. Pressure-gage subassembly for which furnace brazing was combined with solution heat treatment of the 17-7 PH diaphragms (Example 623)

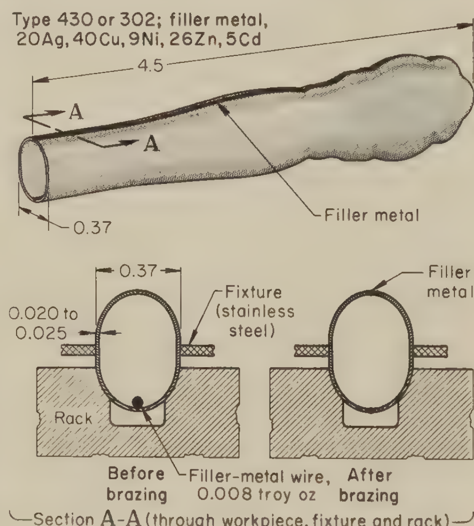
2.8% with the original silver alloy filler metal to 1.0% with the BAg-19 filler metal. Field corrosion returns dropped 96%. The decrease in rejections due to leakage saved $10,000 per year. In addition, $22,500 per year in labor and overhead was saved by the elimination of fluxing. By eliminating the stains caused by flux, it was no longer necessary to paint the assemblies. A summary of processing data is given in the table with Fig. 9.

Example 624. Use of a Special Filler Metal for Color Matching in the Brazing of Tableware Handles (Fig. 10)

To enhance the appearance of brazed tableware handles, it is desirable to match the color of the filler metal to that of the base metal, thereby de-emphasizing the brazed seam. For this purpose, a special filler metal containing 20% silver, 40% copper, 9% nickel, 26% zinc, and 5% cadmium was selected to braze the shells of stainless steel tableware handles, such as that shown in Fig. 10. This nickel-containing filler metal is not susceptible to crevice corrosion. The shells, which were made of either type 430 or type 302 stainless, were furnace brazed in a dissociated-ammonia atmosphere, using a type 3A flux.

The shell halves from which handles were made were formed and coined in a drop hammer, and flash was trimmed in a press. Trimmed edges were ground smooth on a belt grinder. Using a printing-type rubber roller, a light coating of type 3A flux was applied to the joint surfaces of each shell half. Two shell halves were then held together in a lightweight stainless steel fixture, which made contact near the middle of the shells without contacting the joints, a piece of filler-metal wire weighing 0.008 troy oz was placed inside the shell, and the shell was placed on a rack, each side of which had a series of notches into which the shells rested without contacting the joint (see section A-A in Fig. 10).

Racks were placed on the conveyor belt of an electric muffle furnace and were carried into the heating zone, where they remained for 4½ to 6 min at a temperature of about 2000 F. Shells were heated and cooled under protection of dissociated ammonia. After brazing, flux residue was removed from the shells with hot water. Additional brazing conditions are given in the table with Fig. 10.



Furnace Brazing in Dissociated Ammonia

Furnace	Muffle (electric); chain conveyor
Furnace temperature	2000 F
Filler metal	0.008-troy-oz length of wire(a)
Flux(b)	AWS type 3A
Joint preparation	Belt grinding
Brazing time	4½ to 6 min

(a) Filler metal, of composition as noted at top left in illustration, melts at 1150 F and flows at 1750 F. (b) Applied by rubber roller to joint surfaces.

Fig. 10. Brazed tableware handle for which a special filler metal was selected, for good color match (Example 624)

In 90% of the assemblies, capillary action was complete and the entire seam was satisfactorily brazed. The remaining 10% required rebrazing because of incomplete filling in the upper joint. These handles were rebrazed by turning them 180° so that the unfilled portion of the seam was at the bottom; no additional filler metal was used. Only about 1% of the rebrazed handles failed to produce an acceptable joint.

Furnace Brazing in Argon

Argon is occasionally used as a furnace atmosphere in brazing stainless steels to other stainless steels or to reactive metals such as titanium (see Example 625, which follows). Argon has the advantage of being chemically inert with respect to all metals; thus, it is a useful protective atmosphere for metals that can combine with or absorb reactive atmospheres such as hydrogen. An argon atmosphere has the disadvantage of being unable to reduce oxides; consequently, the surface of stainless steel components must be exceptionally clean and free of oxides when brazed in argon.

Example 625. Brazing of Type 347 Stainless Steel to Titanium in an Argon Atmosphere (Fig. 11)

A manufacturer of jet engines designed a gear-reduction box made of commercially pure titanium. This complicated fabrication was made from assemblies of stampings and machined forgings, most of which were joined by gas tungsten-arc welding in argon-filled welding chambers. However, for joining some assemblies brazing was more appropriate.

A typical assembly that was furnace brazed in argon is shown in Fig. 11. This assembly consisted of a machined forging of commercially pure titanium (AMS 4921), and a length of seamless type 347 stainless steel tubing that was flared or expanded for a distance of approximately 5/16 in. to accept the titanium forging. The outside diameter of the titanium forging was held to 0.500 +0.000, −0.001 in. The inside diameter of the stainless steel tube was held

to 0.501 +0.001, −0.000 in. This allowed for a diametral clearance of 0.001 to 0.003 in. between components at room temperature. From 32 to 1650 F, the mean coefficient of expansion of commercially pure titanium is 5.7 micro-in./in./°F; from 32 to 1600 F, the mean coefficient of expansion of type 347 stainless steel is 11.1 micro-in./in./°F. Calculation of the expansion that would occur during heating both components to 1650 F indicated a 0.004-in. diametral clearance between the titanium and the stainless steel. Adding the diametral clearance at room temperature (0.001 to 0.003 in.) to the 0.004-in. clearance gave a total diametral clearance at brazing temperature of 0.005 to 0.007 in., which is within the clearance range commonly recommended for silver brazing.

Silver alloy BAg-19 was selected as the brazing filler metal, because of its high fluidity in an argon atmosphere and because its brazing temperature is lower than that of pure silver. Most alloying elements in silver brazing alloys form brittle intermetallic compounds with titanium, which result in unreliable joints. With the exception of a minute amount of lithium, the only alloying element contained in BAg-19 is 7.5% Cu, and by limiting the time at brazing temperature, sound ductile joints were made and formation of the Ti-Cu intermetallic phase was minimized.

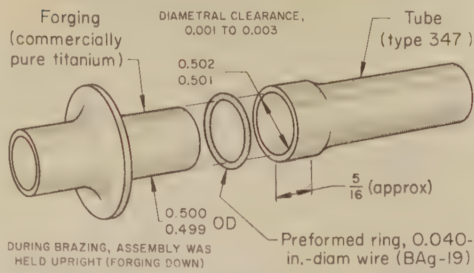
Prior to assembly, the titanium forging was degreased and cleaned in a solution containing 40% nitric acid plus 2% hydrofluoric acid. The stainless steel tubing and the filler metal (preformed rings of 0.040-in.-diam BAg-19 wire) were cleaned by washing in acetone. All subsequent handling of the components during assembly, and until after brazing, was accomplished with the operators wearing clean white lint-free cotton gloves.

The titanium forging was inserted into the expanded end of the stainless steel tube until it was completely seated. A filler-metal ring was placed around the outside diameter of the titanium tube at the joint intersection. The assembly was placed upright (forging down) in a titanium sheet-metal holding fixture and loaded into an Inconel retort. The retort was designed for displacement purging with an inlet and exit manifold for the argon atmosphere. After loading, the retort cover was seal welded to its base, using the gas tungsten-arc process.

The retort was purged for 30 min with pure, dry argon at 150 cu ft per hour, and then was placed in a gas-fired pit-type furnace. The retort was heated to 600 F and held at that temperature for an additional 30 min, or until the dew point of the exiting argon was −70 F, as recorded on an electrolytic water analyzer. The furnace temperature was then raised until the assembly temperature reached 1650 F, as indicated by a Chromel-Alumel thermocouple attached to the titanium holding fixture within the retort. As soon as this temperature was reached, the retort was removed from the furnace and fan-cooled to room temperature.

The retort cover was opened by grinding away the seal weld, and the assemblies were removed. The titanium and stainless steel components emerged bright and clean, with evidence of excellent filler-metal flow. Radiographic inspection showed over 95% joint coverage. All joints were visually inspected on both sides.

Type 347 brazed to commercially pure titanium (AMS 4921); silver alloy filler metal (BAg-19)



Furnace Brazing in Argon

Furnace	Pit, gas-fired(a)
Retort	Inconel, 24-in. diam and length
Fixture material	Titanium sheet(b)
Furnace temperature	1700 ± 10 F
Brazing temperature	1650 ± 10 F
Argon dew points	−85 F (incoming); −70 F (exhaust)
Argon flow rate (purging to cooling)	150 cfh
Filler metal	BAg-19, 0.040-in.-diam wire(c)
Time at brazing temperature	Less than 1 min
Cooling	In argon, to room temperature
Production lot per cycle	1 to 20 assemblies

(a) 72-in. diam, 72 in. deep. (b) Holding fixture, to keep assembly upright (forging down) during brazing. (c) Preformed full ring.

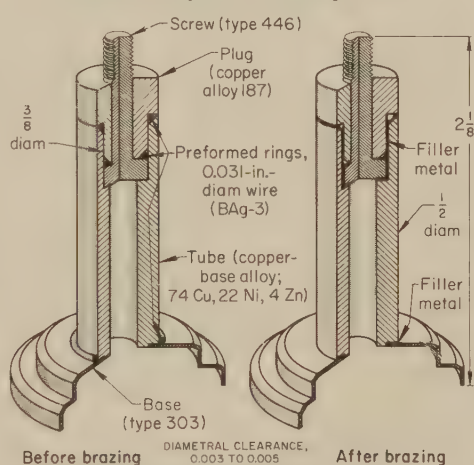
Furnace Brazing in Air Atmosphere

The principal advantages of furnace brazing are that the process provides high production rates and provides a means for using controlled protective atmospheres at controlled dew points, often making it unnecessary to use a flux to obtain satisfactory wetting action. In most furnace brazing applications, both of these advantages are exploited. Occasionally, however, furnace brazing is selected solely on the basis of production rate, and brazing is performed without a protective atmosphere but with a suitable flux. The lower-melting filler metals are generally selected for brazing under these conditions, as in the application described in the following example.

Types 446 and 303, and copper alloy 187 brazed to copper-base alloy (74 Cu, 22 Ni, 4 Zn); type 446 brazed to copper alloy 187 (99Cu, 1Pb); silver alloy filler metal (BAg-3)



Furnace Brazing in Air Atmosphere

Furnace	Continuous belt, air atmosphere
Furnace temperature	1370 to 1450 F
Filler metal	BAg-3, 0.031-in.-diam wire(a)
Flux	AMS 3410D (AWS type 3A)
Time at temperature	1 minute (max)
Production rate	140 assemblies per hour

Furnace Brazing vs Torch Brazing

	Torch	Furnace
Production per hr, assemblies	60(b)	140
Direct-labor rate per hr	$2.40	$2.10
Direct-labor cost per assembly	$0.04	$0.015

(a) Preformed rings, preplaced as shown in illustration. (b) Based on brazing one assembly at a time, with 60-second preparation and heating time per assembly.

Fig. 12. Stainless-and-copper valve bobbin that was furnace brazed in an air atmosphere, when production quantity made furnace brazing more economical than torch brazing (Example 626)

Example 626. Substitution of Furnace Brazing in Air Atmosphere for Torch Brazing (Fig. 12)

The gas-valve bobbin assembly shown in Fig. 12 was satisfactorily brazed by both the torch and furnace processes, the choice of process depending primarily on the production rate required. The cost data given in the table with Fig. 12 are indicative of the differences in rate requirements considered. Labor costs for torch brazing were developed on the basis of a production rate of 60 assemblies per hour, whereas costs for furnace brazing were developed on the basis of a production rate of 140 assemblies per hour. The application of furnace brazing to the bobbin assembly is described in the following paragraphs.

As Fig. 12 shows, the bobbin assembly consisted of four parts: a screw made of type 446 stainless steel; a base made of type 303 stainless steel; a tube made of a copper alloy closely related to nickel silver (74 Cu, 22 Ni, 4 Zn); and a plug, made of copper alloy 187 (99 Cu, 1 Pb), which held the screw in place and blocked gas passage through the tube.

All components were thoroughly vapor degreased before brazing. They were assembled with two preformed rings of 0.031-in.-diam BAg-3 filler-metal wire; the diametral clearance on the joints was 0.003 to 0.005 in. One preform, with a ⅜-in. internal diameter, was placed over the neck of the plug; the other, with a ½-in. internal diameter, was placed over the tube adjacent to the base joint. The joint areas were coated with type 3A brazing flux, and the assemblies were brazed in a continuous-belt conveyor furnace.

Filler metal BAg-3 was chosen in preference to BAg-1 or BAg-1a to avoid the risk of interface corrosion.

Torch Brazing

For stainless steel, the fundamentals of torch brazing, as well as its advantages and limitations, are basically the same as for carbon steels (see the article on Torch Brazing of Steel, which begins on page 619). However, because of the metallurgical characteristics of stainless steel and its requirements for corrosion resistance, best results are obtained when special consideration is given to type of flame at the torch, and to filler-metal composition.

Flame Adjustment. To aid in reducing the oxide already present, as well as to prevent further oxidation of the work-metal surfaces, a strongly reducing flame should be used for torch brazing stainless steel to itself. A reducing flame is also satisfactory for brazing stainless steel to nickel alloys or carbon steels. However, when brazing stainless steel to copper alloys, some compromise is necessary. Normally, a slightly oxidizing flame is best for brazing copper. For brazing stainless steel to copper, the use of a slightly reducing flame is usually a satisfactory compromise.

Filler Metals. The silver alloy filler metals that flow at relatively low temperatures are used almost exclusively for torch brazing of stainless steels. BAg-3 is most often used, because it flows well in the temperature range of 1300 to 1400 F and provides joints that have greater resistance to corrosion

than those brazed with filler metals like BAg-1 or BAg-1a (although these filler metals are also used). The use of filler metals that require temperatures higher than about 1400 F results in excessive oxidation. Sometimes, for special applications, higher-melting filler metals must be used (see Example 615).

Flux of type 3A is used almost exclusively for torch brazing of stainless steel. It has a working range of 1050 to 1600 F, and is well suited for use with the lower-melting silver alloy filler metals. However, in some applications type 3B flux is preferred (see Example 615).

Example of Practice. The example that follows describes typical practice employed for torch brazing stainless steel to unalloyed nickel.

Example 627. Torch Brazing of Stainless Steel to Nickel (Fig. 13)

The brazed assembly shown in Fig. 13, which consisted of a type 304 stainless steel tube and a pure nickel tube, was resistance heated in service. Requirements for this assembly were as follows:

1 To transmit electricity without developing hot spots
2 To be straight and smooth, because it had to slide into a larger assembly
3 To be joined at minimum temperature, because numerous small insulated wires (not shown in Fig. 13) were in the assembly at the time of joining and were subject to damage if the joining temperature was too high.

Torch brazing with silver alloy filler metal proved to be a desirable way to make the joint, because of the relatively low brazing temperature, high electrical conductivity of the joint brazed with the silver alloy filler metal, minimum distortion, ease of removing excess filler metal, and ease of radiographic inspection.

The joint design, shown in Fig. 13, provided for preplacement of the filler metal (BAg-1a) in a ⅛-in.-wide groove machined into the shoulder of the nickel tube. The filler metal was then melted with a torch, and both filler metal and shoulder were machined to match the inside diameter of the stainless steel tube (zero-clearance fit).

For brazing the nickel tube to the stainless steel tube, several heating methods were tried, including induction heating in an inert gas, and multiple-torch heating. However, the most successful method proved to be the use of a single oxyacetylene torch by a skilled technician.

The sequence of operations for single-torch brazing was as follows:

1 Components were cleaned with acetone.
2 Flux paste was placed on the nickel tube in the area to be brazed.
3 The two tubes were assembled in a fixture with a 0.005-in. gap showing at the surface (see detail A in Fig. 13).
4 The assembly was heated with a torch until the filler metal flowed to the outside surface (flow temperature of BAg-1a is 1175 F).
5 Excess flux that flowed to the surface was removed manually.

It was possible to inspect the entire joint by making two radiographs. Only scattered porosity was detected in routine radiographic inspection of the brazed joints.

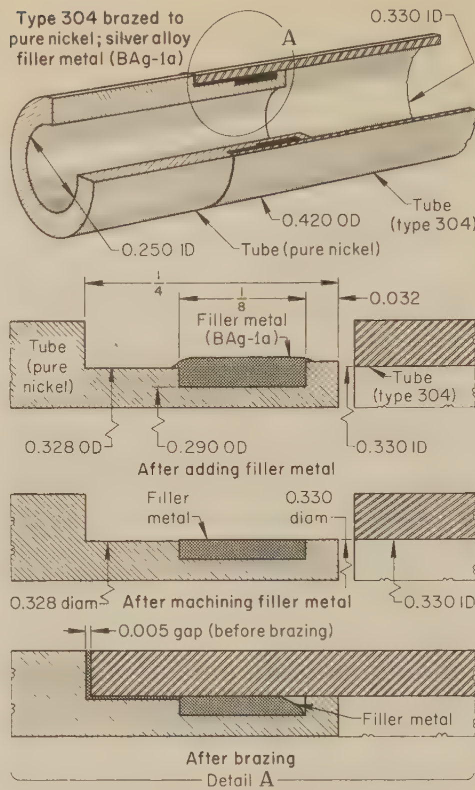


Fig. 13. Torch brazed assembly of a stainless steel tube and a pure nickel tube (Example 627)

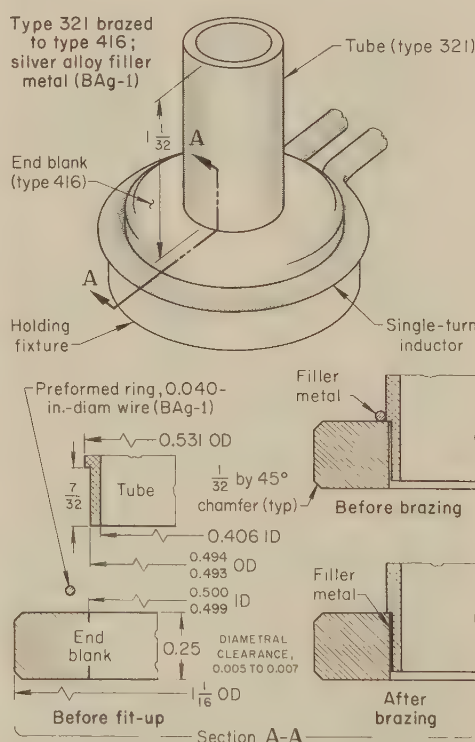
Induction Brazing

Depending on the metallurgical and physical properties of particular stainless steels, their behavior in heating by electrical induction may differ considerably from that of carbon and low-alloy steels and from that of the more widely used nonferrous metals. Further, depending on whether a stainless steel is magnetic or nonmagnetic at room temperature, the response of the steel to induction heating will vary considerably. Differences in specific heat and electrical conductivity will markedly affect response to heating by induction.

In general, because ferritic and martensitic (series 400) stainless steels are ferromagnetic at all temperatures up to the Curie temperature, they will — given the same power input — heat faster than austenitic stainless steels, which, in the annealed condition, are nonmagnetic. (Cold working may induce slight magnetism in the austenitic chromium-nickel steels, whereas the series 400 chromium steels are strongly magnetic.) Rate of heating to the temperature at which the filler metal flows will usually affect induction-coil design and coupling and may also influence selection of power-output frequency and other processing variables (see the article on Induction Brazing, which begins on page 631 in this volume).

Stainless steels may be induction brazed in an air atmosphere, using a suitable flux, although for critical applications induction brazing is sometimes done in a protective atmosphere, or in vacuum (see subsequent discussion under "Induction Brazing in Vacuum", and Fig. 16). In other applications, an inert gas such as argon may be used as a backing gas (as is often done in arc welding), to minimize oxidation (see Example 629).

Examples of Practice. The two examples that follow describe procedures used for induction brazing different types of stainless steel.



Conditions for Induction Brazing

Power supply	Vacuum tube, 20 kw, 450 kHz
Inductor	Single-turn, copper tube
Brazing temperature	1200 F
Filler metal	BAg-1, 0.040-in.-diam wire
Flux	AWS type 3A
Time at brazing temperature	10 sec
Cooling time	10 sec in fixture
Production rate	140 assemblies per hour

Fig. 14. Induction brazed assembly of tubes of types 321 and 416 stainless steel (Example 628)

Example 628. Brazing a Type 321 Tube to a Type 416 End Blank (Fig. 14)

The assembly shown in Fig. 14, part of a solenoid, consisted of a type 321 stainless steel tube brazed to a type 416 end blank. Type 321 is an austenitic stainless steel, whereas type 416 is martensitic and ferromagnetic. Consequently, although both metals were easily brazed, achieving proper joint clearance between the two components was complicated by the marked differences in coefficients of thermal expansion of the two steels. Thus, it was necessary to make calculations to determine the room-temperature clearance that would be required in order to provide suitable clearance at the brazing temperature.

Because the assembly was not intended for high-temperature service, it was preferable to select a low-melting silver alloy filler metal, BAg-1, and a relatively low brazing temperature, 1200 F, in order to minimize heating and oxidation of the stainless steel components. For brazing at 1200 F, calculations based on coefficients of thermal expansion showed that the following dimensions and tolerances in the joint area would be satisfactory: for the tube diameter, 0.494 +0.000, −0.001 in.; and for the inside diameter of the end blank, 0.500 +0.000, −0.001 in. Thus, diametral clearance at room temperature was 0.005 to 0.007 in.

The shape of the assembly and the low brazing temperature both favored brazing by induction. The end blank was in the hardened-and-tempered condition prior to brazing, and the short induction heating cycle (10 sec) did not reduce the hardness to less than the required minimum.

Prior to brazing, the components were vapor degreased. The end of the tube was dipped in flux and inserted in the end blank. A preformed ring of filler-metal wire was slipped over the tube and located at the top of the joint. Then the end blank was placed on a holding fixture and positioned in a single-turn inductor, as shown in Fig. 14, and heated for 10 sec. After

brazing, the assembly was cooled in air for 10 sec before it was removed from the holding fixture; it was then washed in hot water to remove the flux residue. Additional brazing conditions are given in the table with Fig. 14.

Example 629. Change From Torch to Induction for Brazing Ten Joints at a Time (Fig. 15)

The temperature-sensor assembly shown in Fig. 15, consisting of types 302, 303 and 304 stainless steel components, had formerly been joined by torch brazing, using an oxyacetylene torch. Torch brazing was slow, and more time was required for cleaning than for assembly. A change in design forced a change to another brazing technique, and induction brazing was chosen as the most compatible with the BAg-7 filler metal used, as well as being fast and efficient. A special fixture was used to backfill the interior of the assembly with argon during the brazing cycle.

The seven-step sequence of operations was as follows:

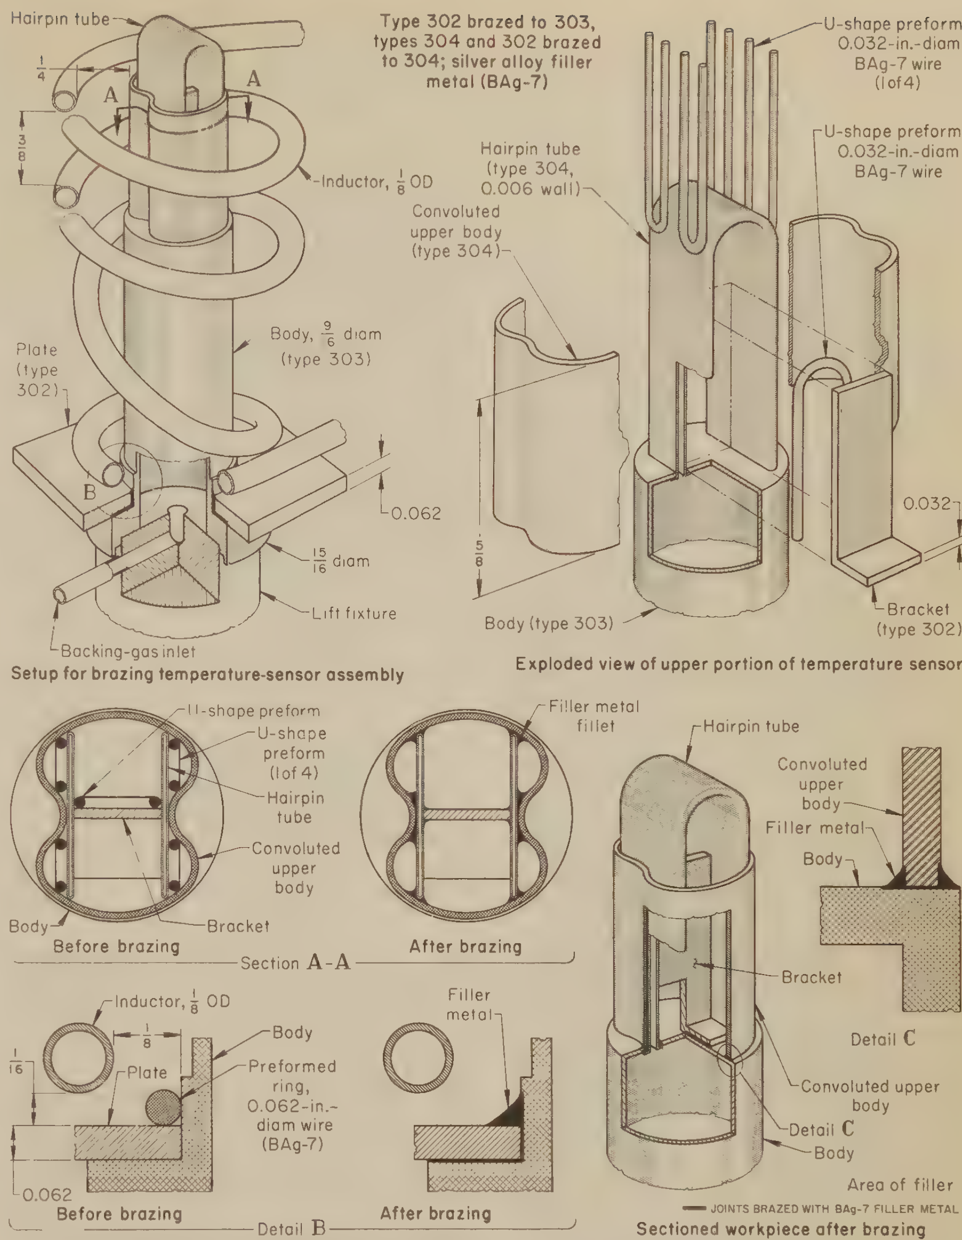
1 Components were hot vapor degreased.
2 Components were etched in an acid solution (3% hydrofluoric acid, 10 to 15% nitric acid, remainder water) at 140 F, for 1 minute (max). They were rinsed, first in a dilute solution of sodium bicarbonate, then in cold water, and finally in alcohol. They were allowed to dry and placed in a clean covered container to await assembly.
3 After assembling, the entire outside of the assembly was coated uniformly with flux, and filler-metal preforms were dipped in flux and placed in position (see Fig. 15).
4 The assembly was placed on a lift fixture and positioned in the inductor.
5 Power was turned on for 40 sec, and time then was allowed for filler metal to solidify.
6 The assembly was placed in a hot aqueous solution of sodium bicarbonate to dissolve all excess flux, then rinsed in water.
7 The assembly was placed in alcohol to remove water, then on racks to permit the alcohol to evaporate, and finally into clean plastic-covered containers.

Assembly and fluxing were delicate operations. After the parts were assembled, both ends of the rectangular-section hairpin tube were flared to keep it in position. A standard paste brush was used to paint the entire assembly with flux. This required careful application. An excessive amount of flux required too much of the brazing cycle to drive off excess moisture, and not enough time was left for brazing. Too little flux would require overheating the fragile assembly to obtain wetting.

Coil design was important in the success of this brazing procedure. The upper portion of the assembly, because of thin sections, came to brazing temperature quickly, whereas the comparatively bulky base heated more slowly. To deal effectively with these conditions, the coupling between coil and workpiece was made much closer at the base than at the top (⅛ in. per side, compared with ¼ in. per side at the top). Two turns were used at the top to spread the heat uniformly along the upper longitudinal joints, whereas a single turn at the base concentrated heat at the single flange-to-tube joint.

The argon backing gas kept the interior bright and clean during the brazing cycle. Operations previously used to remove internal scale were therefore no longer needed. The only postbraze cleaning necessary was a light bead blast to remove stains and discoloration due to handling and to give the product a better appearance.

Induction Brazing in Vacuum. A distinctive advantage of induction brazing, as applied to stainless steel, is that it lends itself to use with simple setups that permit brazing in vacuum. Closed, nonmetallic containers with reasonably good strength and dielectric properties can provide enclosure for the assembly to be brazed and can be evacuated prior to brazing. The inductor can be placed outside the container and can heat the assembly efficiently without being part of the vacuum system.



Conditions for Induction Brazing

Power supply ....Vacuum-tube type(a)	Filler metal ....BAg-7 preforms(b)
Inductor ....Three-turn, ⅛-in.-OD copper tube	Flux ....AWS type 3A
Backing gas ....Argon, at 2 cu ft per hour	Brazing time ....40 sec

(a) Rated at 700 kHz, 1.5 kw; approximately 1 kw was used for this application. (b) Five U-shape preforms of 0.032-in.-diam wire, and one preformed ring of 0.062-in.-diam wire.

Fig. 15. Setup for induction brazing a temperature-sensor assembly, using argon backing, and details of components and joints (Example 629)

Stainless steel collar-and-tube assemblies, such as that shown in Fig. 16, were brazed in a simple setup that combined induction heating and the protection afforded by heating in vacuum. The vacuum container consisted of a high-silica, low-expansion glass tube with copper end fittings, connected to a vacuum system. The collar-and-tube components, with preformed BNi-7 filler-metal rings pressed into place on the shoulder of each collar, were positioned and held inside the glass tube by means of a simple holding fixture. The tube was sealed and evacuated, with a multiple-turn inductor, outside the tube, in position to heat one of the collars. When the vacuum reached 10^{-3} torr, heating was started. The collar was heated slowly to 1775 F, and after 4 min the power was shut off. The tube was then repositioned to bring the second collar into the field of the inductor, and the heating sequence was repeated.

When the second collar had cooled to a black heat (no glow visible in normal light), the tube was backfilled for 5 min with argon. Brazed joints were inspected visually and by dye-penetrant and metallographic methods and were found to be sound and acceptable in all respects. The induction heating source was an 8-kva spark-gap con-

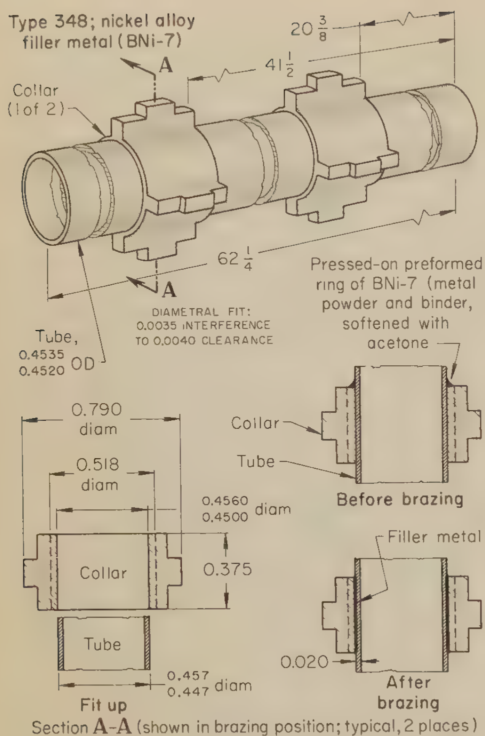


Fig. 16. Collar-and-tube assembly that was induction brazed in vacuum (see text)

verter with an operating frequency of 175 to 200 kHz. The water-cooled external inductor coil was made of ¼-in.-diam copper tubing. Production rate was 22 assemblies per day.

Dip Brazing in a Salt Bath

Brazing of stainless steel by immersion of all or a portion of the assembly in molten salt offers essentially the same advantages that would apply to brazing similar assemblies made of carbon steel, and is likewise subject to the same limitations (see the article on Dip Brazing of Steel in Molten Salt, which begins on page 655).

Example of Practice. The example that follows describes an application for which dip brazing was preferred.

Example 630. Change From Torch or Induction to Dip Brazing, To Reduce Distortion (Fig. 17)

The television wave-guide assembly shown in Fig. 17 consisted of a type 304 stainless steel flange brazed to a tube of copper alloy 230 (red brass, 85%). Satisfactory end use was dependent on a minimum of distortion. When the assembly was brazed by torch or induction, rejection rate sometimes reached 70% because of distortion caused by uneven heating. When dip brazing was adopted, the rejection rate dropped almost to zero.

Prior to brazing, the stainless steel flange was degreased and pickled, and the brass tube was degreased and bright dipped. Then the flange was placed on the tube, the tube end was flared outward slightly, a preform of the filler metal was placed over the tube adjacent to the flange, and AMS 3410D (AWS type 3A) flux was applied to the joint. The assembly was suspended flange-down over an electrically heated salt bath to preheat the flange and dry the flux. The assembly was then lowered slowly into the molten bath for a distance of about 1 in. above the flange. The molten bath was maintained at 1350 F. The assembly was held in the bath for 1½ min, and was then removed and air cooled. The flux residue was removed by rinsing the assembly in water at 140 F. Production rate was 30 assemblies per hour.

Electron Beam Brazing

Electron beam welding equipment and techniques have been used to a limited extent for brazing. The high vacuum used in the work chamber (10^{-4} to 10^{-5} torr) permits adequate flow of brazing filler metal on properly cleaned joints without using a reducing atmosphere or a flux. There is no problem of flux entrapment, and no need to clean the work after brazing. The high vacuum and the absence of flux provide a brazing environment that avoids the problems associated with prepared atmospheres when brazing some stainless steels, as well as the more reactive metals such as titanium.

Electron beam brazing is done in the same way as electron beam welding, except that the beam is defocused to provide a larger beam spot and to reduce the power density (kilowatts per square inch) or the heating effect on the work. (Electron beam welding is discussed in the article that begins on page 519.) If necessary, the beam spot diameter can be enlarged substantially, depending on the type of equipment (defocused beam; see Example 631), while providing an adequate amount of heat input for brazing. Work movement can be used if an area substantially larger than the beam spot size is to be heated, and the work can be rotated under the beam for uniform heating.

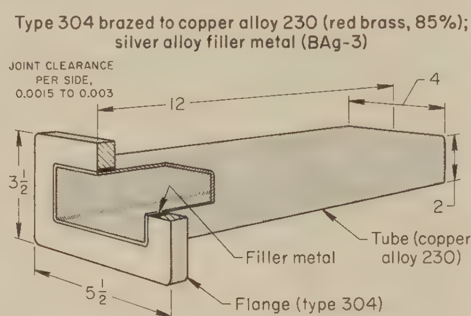

Fig. 17. Television wave-guide assembly joined by dip brazing in a salt bath, to avoid high incidence of distortion that had occurred in torch and induction brazing (Example 630)

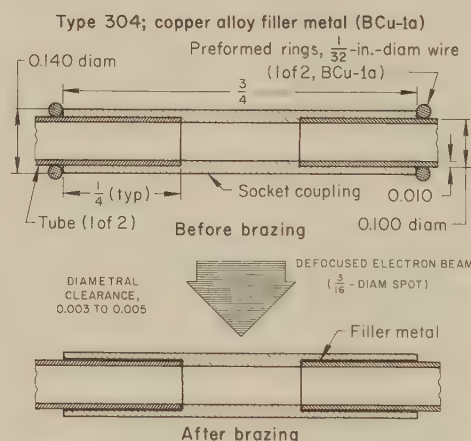

Conditions for Electron Beam Brazing

Joint type	Cylindrical sleeve
Filler metal	¹⁄₃₂-in.-diam wire, BCu-1a
Machine capacity	3 kilowatts
Gun type	Fixed diode
Vacuum chamber	24-in. diam
Maximum vacuum	10^{-5} torr
Fixtures	Holding jig
Pumpdown time	30 min
Brazing power	18 kv, 20 to 30 ma
Beam spot size	³⁄₁₆-in. diam (approx)
Brazing vacuum	10^{-5} torr
Brazing time	30 sec

Fig. 18. Joint between two capillary tubes of an instrument package that was electron beam brazed using a low-power defocused beam in a high vacuum (Example 631)

Brazing temperatures are reached quickly, and heat can be localized to minimize grain growth, softening of cold worked metal and, in austenitic stainless steels, sensitizing of the material by carbide precipitation.

Applications. Electron beam brazing is a convenient method for brazing small assemblies such as instrument packages, combining the versatility and close controllability of electron beam heating with the advantages of vacuum brazing. Packaged devices can be encapsulated with an internal vacuum without damaging the basic package.

Tube-to-header joints in small heat-transfer equipment made of heat-resisting alloys and refractory metals are sometimes electron beam brazed. In one technique, the tube-to-header joint is electron beam welded on the top side of the header, and brazing filler metal preplaced on the reverse side of the header at the joint is caused to melt and flow by the heat of the beam.

Small-diameter, thin-wall stainless steel tubes are readily joined by electron beam brazing, as in the example that follows.

Example 631. Use of Defocused Beam for Electron Beam Brazing Small Tubes (Fig. 18)

Capillary and other small-diameter tubes used in instrument packages required leak-tight joints to be made without overheating other portions of the assembly. The use of flux also had to be avoided, since entrapped flux was difficult or impossible to remove. These conditions were met by electron beam brazing.

A typical joint in the 0.100-in.-OD by 0.010-in.-wall type 304 tubing that was brazed by the electron beam process is shown in Fig. 18. Joint design was based on the use of a ¾-in.-long socket coupling counterbored with a total clearance of 0.003 to 0.005 in. over the tube diameter and to a depth of ¼ in. Average joint clearance (per side) was therefore 0.002 in. Tubes and socket coupling were deburred and solvent cleaned, and assembled with two wire-ring preplacements of BCu-1a filler metal as shown in Fig. 18. The tubes were held in position with a small clamping fixture, and the assembly was mounted in a fixed position on a table in the vacuum chamber.

After pumpdown, the joint was brought to brazing temperature by moving the table back and forth under the defocused electron beam so that the heat of the ³⁄₁₆-in.-diam beam spot was applied chiefly to the central portion of the coupling. Heated by conduction at relatively low beam power, the filler metal melted and flowed through the joint in approximately 30 sec.

About ten assemblies were brazed, one per pumpdown, using the machine settings and other brazing conditions given with Fig. 18.

Sensitizing of the austenitic stainless steel was not a problem in this application, because the service environment was not significantly corrosive. However, the relatively short-time brazing cycle minimized grain growth, as well as dilution of the thin-wall tubing with copper filler metal.

Brazing of Aluminum Alloys

BRAZING of aluminum alloys was made possible by the discovery of fluxes that disrupt the oxide film on aluminum without harming the underlying metal, and by the development of filler metals (aluminum alloys) with suitable melting ranges and other properties.

The aluminum-base filler metals used for brazing aluminum alloys have liquidus temperatures much closer to the solidus temperature of the base metal than do those for brazing most other metals. For this reason, close temperature control is required in brazing aluminum. The brazing temperature should be approximately 70 F below the solidus temperature of the base metal, but if temperature is accurately controlled and the brazing cycle is short, it can be as close as 10 F. Aluminum alloys, depending on composition, can be brazed with commercial filler metals from 1020 to 1180 F. Most brazing is done at temperatures between 1040 and 1140 F.

Much of the equipment and many of the techniques used to prepare, braze and inspect aluminum alloys are the same as those used for other metals; the reader may refer to the articles on Furnace Brazing, Torch Brazing, Resistance Brazing and Dip Brazing of Steel in Molten Salt in this volume for general information.

Base Metals

The non-heat-treatable wrought alloys that have been brazed most successfully are the 1*xxx* and 3*xxx* series, and low-magnesium members of the 5*xxx* series. The alloys containing a higher magnesium content are more difficult to braze by the usual flux methods, because of poor wetting by filler metal and excessive penetration. Filler metals are available that melt below the solidus temperatures of most commercial wrought non-heat-treatable alloys.

Of the heat treatable wrought alloys, those most commonly brazed are the 6*xxx* series. The 2*xxx* and 7*xxx* series of aluminum alloys are low melting and, therefore, not normally brazeable, with the exception of 7072 (used as a cladding material only) and 7005.

Alloys that have a solidus above 1100 F are easily brazed with commercial binary aluminum-silicon filler metals. Stronger, lower-melting alloys can be brazed with proper attention to filler-metal selection and temperature control, but the brazing cycle must be short to minimize penetration by the molten filler metal. Sand and permanent mold casting alloys with a high solidus temperature are brazeable; the most commonly brazed are 43, 356 and 612. Formerly, aluminum die castings were not brazed because of blistering due to high gas content, but recent advances in casting technique have resulted in improved quality.

Some common wrought and cast aluminum alloys, along with their melting temperature ranges and brazeability ratings, are listed in Table 1.

Brazing of aluminum is generally limited to parts more than 0.015 in. thick, but dip brazing and fluxless vacuum brazing have been done successfully on aluminum as thin as 0.006 in.

Table 1. Melting Ranges and Brazeability of Some Common Aluminum Alloys

Alloy	Melting range, F	Brazeability(a)
Non-Heat-Treatable Wrought Alloys		
EC	1195 to 1215	A
1100	1190 to 1215	A
3003(b)	1190 to 1210	A
3004	1165 to 1205	B
5005	1170 to 1205	B
5050	1160 to 1205	B
5052	1100 to 1200	C
Heat Treatable Wrought Alloys		
6053	1100 to 1205	A
6061	1100 to 1200	A
6063	1140 to 1210	A
6951(c)	1140 to 1210	A
7005	1125 to 1200	B
Casting Alloys(d)		
43	1065 to 1170	B
356	1035 to 1135	B
A612	1105 to 1195	B
C612	1120 to 1190	A

(a) A, generally brazeable by all commercial procedures; B, brazeable with special techniques or in specific applications that justify preliminary trials or testing to develop the procedure and to check the performance of brazed joints; C, limited brazeability. (b) Used both plain and as the core of brazing sheet. (c) Used only as the core of brazing sheet. (d) Sand and permanent mold castings only.

Filler Metals

Commercial filler metals for brazing aluminum are aluminum-silicon alloys containing 7 to 12% Si. Lower melting points are attained, with some sacrifice in resistance to corrosion, by adding copper and zinc. The compositions and melting ranges of the most commonly used brazing filler metals for aluminum are given in Table 2.

The optimum brazing-temperature range for an aluminum-base filler metal not only is determined by the melting range of the filler metal and by the amount of molten filler metal needed to fill the joint, but also is limited by the mutual solubility between the filler metal and the base metal being brazed. The brazing-temperature ranges of some filler metals are related to those of some base metals in Fig. 1.

Filler metals to be applied separately from the base metal to be brazed are available as wire and sheet (thin-gage shim stock). The manufacture of filler metal in sheet and wire forms becomes more difficult as the silicon content increases. Only filler metals BAlSi-2 (alloy 4343), BAlSi-4 (alloy 4047), and alloy X4003 are available as sheet.

Most filler metals are used for any of the common brazing processes and methods, but one (alloy X4003, which contains an addition of magnesium and has a brazing-temperature range of approximately 1110 to 1130 F) has been developed exclusively for use in fluxless vacuum brazing. Another, a proprietary mixture of filler metal BAlSi-4 (alloy 4047) in powder form and a chemical compound, is used exclusively with dip

Table 2. Compositions and Melting Ranges of Brazing Filler Metals for Use on Aluminum Alloys

AWS-ASTM class	Alloy	Product form	Principal alloying elements, % Si	Cu	Mg	Zn	Approximate melting range, F
BAlSi-2	4343	Sheet, cladding	7.5	...	...	...	1070 to 1135
BAlSi-3	4145	Wire, flattened wire	10	4	...	...	970 to 1085
BAlSi-4	4047	Wire, sheet	12	...	...	...	1070 to 1080
BAlSi-5	4045	Cladding	10	...	...	...	1070 to 1095
...	X4003	Wire, sheet, cladding	7.5	...	2.5	...	1010 to 1110
...	4245	Wire	10	4	...	10	960 to 1040

brazing. This mixture can be brushed or extruded onto the joints and can be applied to parts in all positions. The mixture stays in place because it is baked onto the metal surface during preheating. It may be employed in brazing overhead joints in wave-guide assemblies and in applications where a small, controlled flow of aluminum alloy filler metal is desired.

Brazing Sheet

Brazing sheet consists essentially of one or more coatings or interlayers of filler metal (usually an aluminum-silicon alloy) roll bonded to one or more sheets of structural aluminum alloy. Brazing sheet provides a more convenient method of supplying the filler metal than wire, shims or powder; it is particularly convenient for mass-produced, complex assemblies. However, the choice to use brazing sheet instead of filler metal in other forms is based on cost in a given application. Brazing sheet can be subjected to drawing, bending or any other forming process that does not break the bond between the filler metal and the structural alloy that compose the sheet.

Four types of brazing sheet are shown in Fig. 2. The most common type (Fig. 2a) has filler metal on one or both sides. The compositions and brazing-temperature ranges of commercially available brazing sheets of this type are listed in Table 3.

The three other types of brazing sheet shown in Fig. 2 are available only on special order. The type shown in Fig. 2(b) has structural alloy sheets on both sides of an interlayer of filler metal; a slot is machined into the structural alloy sheet on the joint side, to permit flow of filler metal. The brazing sheet shown in Fig. 2(c) has an interlayer of aluminum alloy to act as a diffusion barrier between the high-silicon filler metal and the core sheet of structural alloy (see discussion headed "Silicon Diffusion", on page 678). The brazing sheet shown in Fig. 2(d) has filler metal on the joint side of the structural alloy and is alclad, for corrosion resistance, on the opposite side.

The structural alloys commonly used in brazing sheet are 3003, which is resistant to sagging at brazing temperatures, and 6951, which is heat treatable after brazing and is used where higher strength is desired. Some of the commercially available filler metals are used as cladding of brazing sheet.

Fluxes

Conventional brazing, performed in air or other oxygen-containing atmosphere, requires the use of a chemical flux. Fluxes, which become active before brazing temperature is reached, and which are molten over the entire brazing range, penetrate the film of oxide, exclude air, and promote wetting of the base metal by the filler metal. A satisfactory flux must (*a*) begin to melt at a temperature low enough to minimize oxidation of the parts, (*b*) be essentially molten at the time the filler metal melts, (*c*) flow over the joint and the filler metal to shield them from oxidizing gases, (*d*) penetrate the oxide films, (*e*) lower the surface tension between the solid and liquid metals to encourage wetting, (*f*) remain liquid until the filler metal has solidified, and (*g*) be relatively easy to remove after brazing is complete.

A superior flux for furnace and torch brazing will melt at a temperature only slightly lower than the melting temperature of the filler metal, ensuring uniform wetting and flow of filler alloy in minimum time. A flux to be used as a dip brazing bath is compounded to be molten and stable at the melting temperature of the filler metal. In addition, a flux for use in dip brazing should form only minimum quantities of solid particles or sludge that sink to the bottom of the bath or collect in joint interstices. Since the parts are totally immersed in flux during dip brazing and oxygen cannot reach the surfaces of the parts to re-form oxide, less active fluxes can be employed for dip brazing than for torch or furnace brazing. Physical properties of typical fluxes are given in Table 4.

Fluxes for use in brazing aluminum alloys usually consist of mixtures of alkali and alkaline earth chlorides and

fluorides, sometimes containing aluminum fluoride or cryolite ($3NaF \cdot AlF_3$). The compositions are adjusted to give a favorable balance between melting range, density, chemical activity, etching characteristics, and cost. Small amounts of one or more of the chlorides of antimony, cadmium, chromium, cobalt, copper, iron, lead, manganese, nickel, silicon, tin, zinc, precious metals, or rare earths improve the performance of fluxes. Absence of fluoride prevents effective oxide removal, but too high a concentration results in an undesirably high melting range.

Flux is received in dry powder form in sealed, moistureproof containers. It can be stored for long periods if the seal is maintained. Once a flux container is opened, the utmost care must be taken to prevent contamination of the flux. Flux containers should be of perfectly clean aluminum, glass or earthenware — *never* of steel.

Aluminum brazing fluxes can be applied dry, or they can be mixed with tap water or alcohol and be applied by painting, spraying or dipping. Dry flux can be sprinkled on the work, or a heated filler rod can be dipped into the dry flux. Although flux can be mixed with tap water to form a paste, the use of alcohol may be preferred in some applications. Where vapor pressure from drying flux may cause dislocation of the filler metal or the assembly, the use of alcohol will minimize this effect.

Although 45 minutes can be considered as the maximum time lapse between the application of flux and subsequent brazing, it is recommended that the flux be applied immediately prior to brazing. When wet flux mixtures are used, they should be freshly prepared (at least once in each shift).

The wetting action of a flux can be improved considerably by the use of a wetting agent. A mixture of two-thirds flux and one-third water by weight usually is satisfactory for painting. Spraying or dipping will require a thinner consistency with more water being added. The amount of water needed to suit the spray gun used is best determined by trial.

Flux Stop-Offs. Sometimes it is desirable to take positive action to prevent filler metal from flowing beyond a certain area. Stop-offs suitable for this purpose usually consist of a mixture of equal parts by weight of a medium-heavy engine oil (SAE 30), finely powdered graphite, and benzene or naphtha (mineral spirits). Often, a mark made by a soft graphite pencil is an effective stop-off. Proprietary, commercial stop-off compounds are also available. Some of these may be applied in paste form without being baked, and later may be removed by brushing.

Furnace and dip brazing frequently require the use of a stop-off to prevent the jigs and fixtures from being brazed to the work. The mixture is brushed or sprayed on the areas to be stopped off and then baked at 400 to 600 F to carbonize the oil. One application will usually last for several brazing cycles. Stop-offs for fluxless vacuum brazing are usually refractory oxides, which are sprayed on the jigs and fixtures, or are formed on them by heating to high temperature in an air atmosphere.

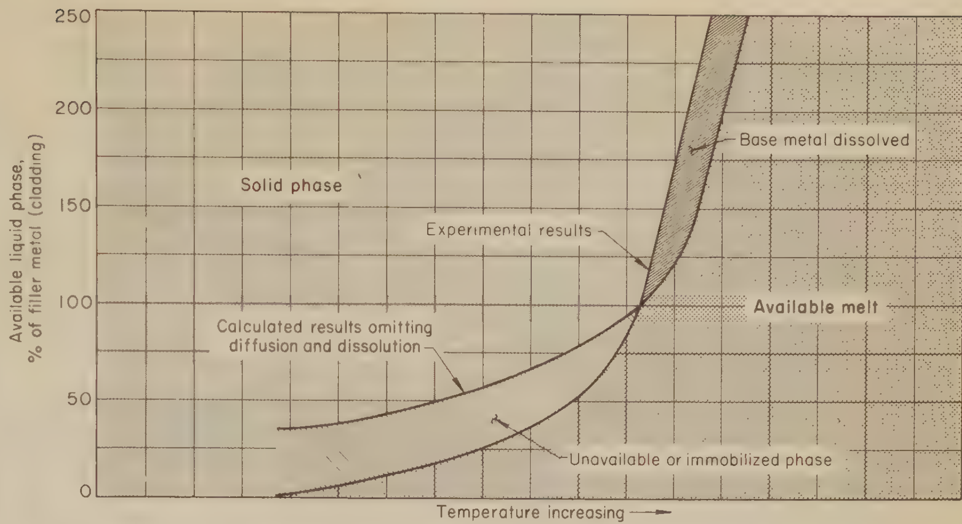

Fig. 5. Effect of temperature on availability of liquid phase from aluminum brazing sheet. See text for discussion.

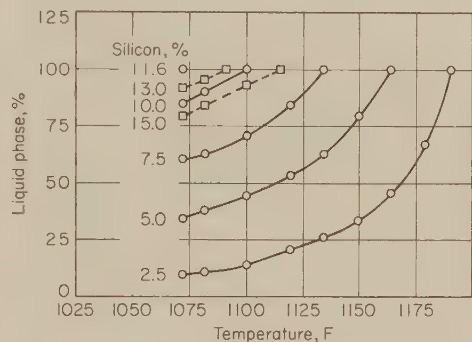

Fig. 6. Effect of temperature and silicon content on percentage of liquid phase available, for aluminum-silicon alloys (calculated)

Table 4. Physical Properties of Typical Fluxes for Brazing Aluminum Alloys

Property of flux	Dip brazing (Flux 33)	Torch and furnace brazing (Flux 34)
Solidus temperature, F	900	915
Liquidus temperature, F	1035	1115
Density at 1100 F, lb per cu ft	104	107
Specific heat, Btu per lb per °F (approximate)	0.2	(a)
Heat of fusion, Btu per lb (approximate)	168	(a)
Heat requirement, Btu to heat 1 lb of flux from solid at 70 F to liquid at 1150 F (approximate)	385	(a)
Resistivity, ohm-cm at:		
1080 F	0.43	(a)
1130 F	0.36	(a)
1150 F	0.33	(a)
1180 F	0.29	(a)

(a) These properties are not pertinent to torch and furnace brazing.

Such coatings generally last until mechanically damaged. In torch brazing, the use of stop-offs is not required, because the operator has adequate control over the flow of filler metal.

Fillet Formation

The major requirement of brazing is to adjust conditions so that gravity and capillarity cause molten brazing filler metal to flow through the full length of the joint and form fillets. The effects of gravity are often influenced by the buoyant action of molten flux, as in dip brazing. The density of the molten flux is usually only slightly less than that of molten filler metal.

In an inert gas or in vacuum, the surface tension of some aluminum brazing alloys is about 850 dynes per centimeter; in the presence of a brazing flux, it is about 650 dynes per centimeter. The addition of metallic wetting agents, such as the magnesium that is alloyed in X4003 filler metal, will effectively lower the surface tension to the range of 500 to 700 dynes per centimeter, without the presence of a brazing flux.

The microsection shown in Fig. 3, taken through a T-joint in which the vertical member was No. 22 brazing sheet (both sides clad with filler metal), shows the two fillets of filler metal to have the shape of almost perfect arcs of a circle. In an experiment on T-joints of this kind, fillet heights and widths were measured; the results are plotted in Fig. 4. As Fig. 4 shows, fillet heights and widths were equal up to approximately 0.15 in.; beyond that point, as the width increased, the height approached a maximum value of 0.30 in., which agrees with the value calculated from the surface tension.

In another experiment, T-joints in which the *horizontal* member was brazing sheet, clad on the joint side with filler metal, were heated to various temperatures, and the amount of flow of filler metal was measured. The results are shown in Fig. 5, together with the results of calculations based on the known character of the filler metal. These experimental data show that at a certain temperature, 100% of the filler metal (cladding) will flow. This is the point at which the dissolution of the base metal by the filler metal is equal to the absorption of filler metal by the base metal. As the temperature rises above this point, the molten filler metal dissolves more base metal from the brazing sheet, causing an increase in the amount of molten phase until, at the melting point of the base metal, all of the brazing sheet is molten.

As the temperature is lowered from the point indicating 100% flow, more and more of the molten phase is im-

mobilized by capillary forces in the increasing number of solid particles, and the flowability of the molten phase decreases. The temperature of 100% flow depends on composition and thickness of filler-metal cladding and base-metal core, specific flux used, type of joint to be brazed, length of the flow path, and time at temperature.

Figure 6 gives the calculated percentage of liquid phase available at several temperatures for aluminum-silicon filler-metal alloys of various silicon contents. The amount of liquid phase, of course, increases with silicon concentration up to the eutectic composition (11.6%), and with temperature. Although the eutectic composition at first appears to be optimum for filler metal, commercial practice usually employs a lower-silicon filler metal. This permits control of fillet size by temperature control, as the amount of filler metal melted depends on temperature. Figure 7 shows the amount of filler metal that flows from the interlayer of a sheet. Although from Fig. 6 all of an Al-10Si filler metal should be available for flow at 1100 F, only 25% flow was actually found in the experiment.

Silicon Diffusion. A limitation to the general application of brazing sheet is imposed by diffusion between the core metal and the coating of filler metal. Long heating times increase diffusion of silicon from the coating into the core, which can lower the mechanical properties of the core and can reduce the amount of filler metal available for flow. Figure 8 shows temperature and duration of heating for the production of 0.0005 and 0.0015-in. silicon-depleted zones in coatings of alloys Al-7.5Si and Al-12Si on brazing sheet. Brazing sheet clad with Al-7.5Si heated at 1040 F for 9 hr is shown as having a depleted zone of 0.0015 in. Thus, in theory, 0.015-in. No. 11 and 12 brazing sheets, which have a nominal cladding of 0.0015 in., could not be brazed if subjected to this temperature for this long a time, because all the silicon would have diffused into the core. When a No. 12 brazing sheet was heated for 3 hr at 1065 F, the measured thickness of the silicon-depleted zone was 0.0011 in. For Al-7.5Si cladding, Fig. 8 predicts 0.0014 in.

To restrict diffusion, the brazing cycle should be as short and at as low a temperature as possible. Core alloys must be selected to prevent formation of harmful intermetallic compounds. Under conditions where the core material is aggressively penetrated by the coating alloy, an intermediate protective layer of commercial-purity aluminum or of an alloy not easily penetrated by the coating can be used.

Joint Design

Joints to be brazed with the use of flux must be designed to permit application of the flux to the joint surfaces before assembly or to permit entry of the flux between the components after assembly. In addition, provision must be made for the flux to flow out; entrapped flux is a potential source of corrosion. Joint design must also permit the escape of gas and allow subsequent penetration by the filler

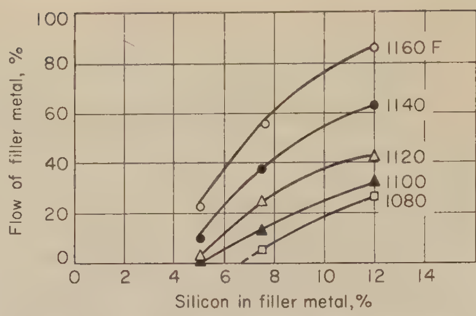

Fig. 7. Flow of filler metal from interlayer of brazing sheet (measured)

metal, and must ensure the complete distribution of filler metal in the joint. (See the section on Joint Fit and Design on page 607 in the article on Furnace Brazing.)

Assemblies to be brazed may be designed with many types of joints. For brazing processes that require a flux, joint strength equal to the strength of the base metal can be obtained with lap joints. The designs of six lap joints for brazing are contrasted with counterpart butt, T and corner joints used for welding in Fig. 31 in the article on Furnace Brazing (see page 610). Lap joints that require the filler metal to flow long distances should be designed so it flows in one direction only, because filler metal flowing from both edges of such joints may entrap flux. (The need for flow in joints having wide laps is nullified by using brazing sheet as one of the members.)

Butt and scarf joints will not usually be as strong as the base metal, but when correctly designed, such joints may give satisfactory service. For fluxless brazing processes, joints having narrow or line contact are preferred to joints having wide contact.

Joints of short length or line contacts are highly desirable during any aluminum brazing process, whether torch, furnace or dip. For long lap joints, corrugations can be used to provide an outlet for molten flux, and the final result is the same as when line contacts are used.

In joints for furnace and torch brazing, capillary rise is limited to about ¼ in. and must be considered in the design of the joint. In joints for dip brazing, capillary rise is seldom a limiting factor in design.

During brazing of aluminum, base metal and filler metal are mutually soluble. This causes the filler metal to change progressively in composition as it flows in joints, which progressively raises the liquidus temperature of the filler metal and reduces the ability of the filler metal to wet and flow. Clearances must be sufficient to prevent premature solidification of the filler metal in small capillary spaces, which entraps flux and causes porosity. The longer the distance the filler metal must flow, the greater the clearance must be.

In dip brazing with preplaced filler metal, joint clearance at room temperature ranging from 0.002 to 0.004 in. may suffice for narrow laps (¼ in. or less). Wider laps may require clearances up to 0.010 in. For furnace and torch brazing, clearance ranging from 0.004 to 0.010 in. is required for narrow laps (¼ in. or less), and as much as 0.025 in. for wider laps. With brazing sheet, clearances may be smaller. To ensure formation of a continuous fillet in fluxless vacuum brazing with brazing sheet, clearances normally should not exceed 0.003 in., but in some applications continuous fillets have been formed in joints with clearances as great as 0.009 in.

Tube-to-tube joints to be torch or furnace brazed require that the outer tube be flared 10° to 12° to produce sound joints. In joining fittings to a tube, knurling of the tube or fitting will permit complete penetration through the joint to be achieved.

When not employing brazing sheet, the correct preplacement of the filler metal is of utmost importance. Gravity is usually sufficient to keep the filler metal in place for fixed-position furnace brazing. In dip brazing, the filler may have to be held in place, because of the buoyancy of the molten flux.

Prebraze Cleaning

Oil and grease must be removed from components of assemblies to be brazed. For non-heat-treatable alloys, vapor or solvent cleaning is usually adequate, although chemical cleaning may be required for components that have been severely formed, as by spinning. For the heat treatable alloys, chemical cleaning is usually necessary, to reduce the amount of tenacious oxide film. (Chemical cleaning is not normally required for fluxless vacuum brazing.) Scrubbing with steel wool, abrasive cloth or a power-driven wire brush (preferably with stainless steel bristles) can also be used. Burrs should be removed before brazing.

Chemical cleaning methods used prior to brazing include nitric acid, hydrofluoric acid, or nitric-hydrofluoric acid mixtures at room temperature. A widely used method is immersion for about 30 sec in a solution containing equal parts of commercial nitric acid and water, followed by rinsing in clean water (preferably hot) and drying in hot air.

Aluminum-silicon alloys require a special etchant, because the silicon constituent is not attacked readily by many alkaline or acid solutions. For these alloys, a room-temperature solution of 3 parts concentrated nitric acid and 1 part concentrated hydrofluoric acid is employed. This solution requires a tank lined with an inert material such as carbon brick or certain types of plastic. The presence of fluorides necessitates caution in handling and special waste-disposal procedures. For thick and resistant oxide coatings, immersion for about 30 sec in a warm (150 F) aqueous solution of 5% sodium hydroxide is recommended. To remove the surface smut produced by this treatment, the treatment should be followed by a cold-water rinse, immersion in a room-temperature solution containing equal parts of commercial nitric acid and water, a final water rinse (preferably, hot), and hot-air drying.

Chemical cleaning of aluminum provides excellent surfaces for brazing. Cleaning in a caustic solution is par-

ticularly effective, although residues from caustic solutions can interfere with brazing — probably because of the large amounts of aluminum oxide formed. Nitric, sulfuric and phosphoric acid residues may prevent brazing entirely. To eliminate the possibility of harmful residues, chemical treatments should be followed by a hot water rinse, after which the components are dried. Hydrofluoric acid residues are not detrimental to brazing, but hydrofluoric acid is ineffectual for removing oil and grease and thus is useful only on components that have been degreased by a solvent or emulsion cleaner.

For best results, brazing should be done immediately after cleaning, or at least within 48 hr. However, if precautionary measures are taken to prevent their contamination, adequately cleaned components do not lose brazing qualities even in several weeks.

See pages 611 to 616 in Volume 2 of this Handbook for more information on methods for cleaning aluminum alloys.

Assembly

Components to be brazed must be correctly located during assembly and be held in position by some type of jigging. Correct jigging is of particular importance in dip brazing, where the displacement of air and the buoyancy of the flux must be considered. Self-jigging, when possible, offers an economic advantage over the cost of design, maintenance and replacement of jigs. Several methods of self-jigging are described and illustrated in the article on Furnace Brazing. Another method (tabs and mating slots) is described in Example 632, on the next page.

Mating surfaces of brazing sheet should not be spot welded for self-jigging, because they can separate in the flux bath. Jigs that may be required to hold the parts in correct alignment must be resistant to the highly reactive molten flux. Low-carbon steel fixtures may have sufficiently long life for a specific job. Aluminum-coated steel has longer useful life.

Because of differential thermal expansion, the aligning jig should be designed with spring relief. Stainless steel and Inconel X-750 are both good materials for such springs; Inconel X-750 will retain more of its spring characteristics at brazing temperatures. Inconel X-750 also has better resistance to corrosion, not only during brazing, but also in postcleaning operations.

Dip Brazing

The best method of heating and fluxing aluminum joints simultaneously is to immerse the entire assembly in a bath of molten flux. This is known as dip brazing, or flux bath brazing. Dip brazing has been used successfully in the manufacture of complex, multiple-joint heat exchangers.

Immersing the entire assembly into molten flux has many advantages. Heat is applied to all parts simultaneously and uniformly. Air is replaced by a buoyant and surface-active environment, promoting brazing filler-metal flow. The uniform temperature permits production assembly of parts with dimensional tolerances as low as ±0.002 in. or even less.

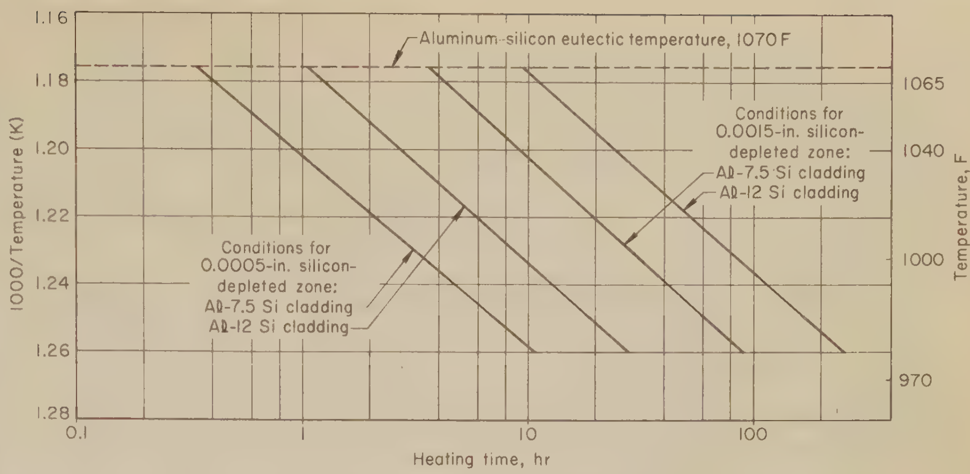

Fig. 8. Effect of heating time, temperature and original silicon content on thickness of silicon-depleted zone in filler-metal cladding

Heat-transfer units assembled from alternate corrugated and flat aluminum brazing sheets or from various crimped and formed pieces are examples of the type of work that dip brazing can handle advantageously. Units weighing up to 20,000 lb have been joined by dip brazing. Certain designs have to withstand a service pressure of 650 psi. Brazing sheet is essential to this type of work, reducing assembly and brazing costs. The rapid and even heating and flux buoyancy minimize distortion.

For assemblies designed with components in close proximity, flux removal can be tedious and expensive. For instance, when components such as those of a heat-exchanger matrix are spaced closer than ⅛ in., the flux holds to the surfaces by surface tension and capillary action; it will not drain from the components freely. This is not as great a problem with spacings greater than ⅛ in. between components of normal length; wider spacing of long components is desirable.

Equipment for dip brazing may be as simple as a heat-resistant glass beaker inside a resistance-heated furnace, or as complex as a large steel vessel lined with high-alumina, acid-proof brick. For adequate resistance to flux, the alumina content of lining brick should be at least 40%. The molten bath is usually heated by low-voltage alternating current passing through the flux between wrought nickel, Inconel 600, or carbon electrodes. These show less attack than copper or copper-bearing electrodes, and cause minimum contamination of the flux. Attack at the electrode-flux-air interface has led to preference for submerged electrodes. The bath temperature should be controlled within ±5 F.

Technique. The amount of flux to fill the bath is about 100 lb per cubic foot. Approximately 385 Btu per pound is required to melt and heat the flux. Thermocouples enclosed in protective tubes should be used to determine the bath temperature, which is the actual temperature of the assembly. There should be enough flux so that the temperature does not drop more than 5 to 10 F when parts are immersed. The specific heat of dip brazing flux, approximately 0.2 Btu per pound per °F, is about the same as that of aluminum. For assemblies that have been preheated to 1000 to 1050 F before immersion in the salt bath, there should be about 16 lb of molten flux per pound of aluminum. With this ratio, the bath temperature may drop 2 to 5 F, and it should be possible to braze four to six loads per hour.

The composition of the flux in the bath should be adjusted periodically by fluoride and chloride additions. Proprietary additive mixtures are available for this purpose. Even when the molten bath is idle, side reactions reduce its activity. Because molten flux may contain water, it should be dehydrated periodically with aluminum to minimize the formation of hydrogen when the assemblies are dipped. The aluminum used for dehydrating the bath may conveniently be a loose coil of alloy 1100 or alloy 3003. When hydrogen stops burning at the surface of the bath, dehydration is essentially complete. Initial dehydration should be conducted for 4 to 48 hr, depending on bath size. Insertion of aluminum in the bath before the brazing operation is begun will also remove heavy-metal impurities such as nickel, copper, iron and zinc. The heavy-metal deposit on the aluminum coil is removed by quenching the coil in water, dipping it in nitric acid, and giving it a thorough water rinse. The coil should be dried before being reused.

These operations, as well as the actual brazing, produce a sludge containing oxides from the brazed parts and the brickwork, and insoluble fluoride complexes. After settling, the sludge should be ladled out at periodic intervals with a perforated tool.

Flux will be removed by dragout on the parts being brazed, and must be replaced. When an assembly is dip brazed, there will be approximately 0.5 oz of flux dragout per square foot of flat surface. With heat exchangers having complex and devious passages, this amount may be larger, because of capillary forces holding the flux. For a specific unit, dragout may vary as much as threefold, depending on the melting point and viscosity of the flux.

Before immersion in the flux bath, all moisture must be removed from the assembly and from any fixture used with it. Even a slight amount of mois-

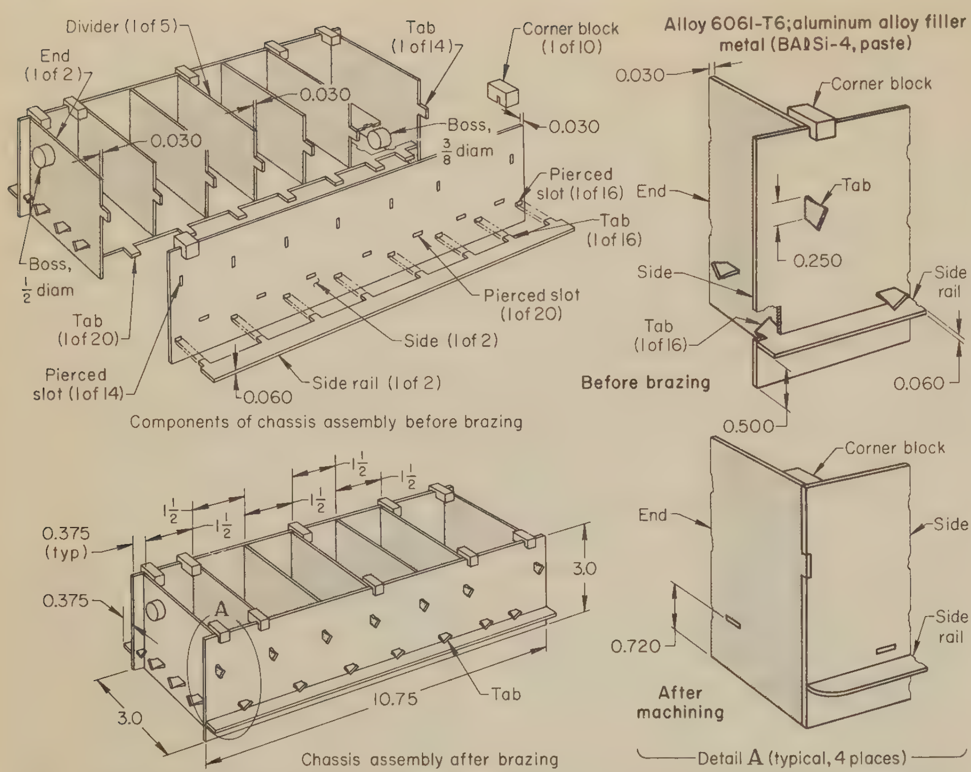

Fig. 9. Dip brazed assembly for an electronic chassis, showing slot-and-tab arrangement for self-jigging (Example 632)

ture can cause spattering in contact with molten flux. Drying by preheating is recommended. The use of preheated assemblies decreases the drop in temperature of the salt bath, shortening brazing time. Large or complex assemblies should be preheated to 1000 to 1050 F, usually in an air-recirculating furnace, at a rate that provides a suitable compromise between distortion from fast heating and diffusion during slow heating. Methods and advantages of preheating are discussed further in the article on Dip Brazing of Steel in Molten Salt, pages 655 to 660.

After being preheated, parts are immediately immersed in the flux bath for the scheduled period. This period will depend somewhat on the mass of the assembly, but immersion is usually only of ½ to 3-min duration. For large assemblies, such as a cryogenic heat exchanger that may weigh more than 1000 lb, immersion time may be as long as 20 min. Time in the bath should be no longer than is required to obtain melting and complete flow of the filler metal. After being preheated, the self-jigged assembly in the following example was dip brazed in only 20 sec.

Example 632. Use of Dip Brazing To Join a Complex Assembly (Fig. 9)

The chassis assembly shown in Fig. 9 was used for airborne electronic equipment. Casting was not a practical method for production of this chassis, because it was a large, thin-wall structure of complex design and the production quantities were small. Resistance spot welding, arc welding and torch brazing were ruled out by the need for a continuous metal surface, close dimensional tolerances and the presence of hidden joints in the design. Dip brazing was selected as the joining method best fulfilling the design requirements.

The dip brazed assembly was made of alloy 6061-T6 as follows. The two ends, two sides, five dividers, two side rails and the bottom were blanked and pierced in a numerically controlled press. The ten corner blocks and the two round bosses were machined from bar stock. Self jigging of the 24 components was achieved by providing the sheet-metal components with slots and mating tabs; the tabs were inserted in the slots, and hand twisted after assembly to hold the components in place. After brazing, the tabs and other extraneous material were machined off (see lower right view in Fig. 9).

This type of assembly allowed brazing with no external fixturing and permitted the use of assembly-line techniques, thus effecting savings of an estimated one fourth to one half of the cost of purchasing the assembly from an outside supplier. Total processing cost (excluding cost of material) was approximately 10¢ per inch of joint, or about $10.00 per assembly.

After burrs larger than 0.005 in. were removed from the sheet-metal components, the chassis was assembled and then cleaned by degreasing followed by immersion in either a caustic bath or a phosphoric acid etching solution. Brazing paste containing BAlSi-4 filler metal was applied to one side of each joint, to ensure against flux entrapment. The assembly was preheated for 20 to 30 min in an electric furnace operating at 1000 F, and then was dipped for 20 sec in a bath of proprietary brazing flux electrically heated to 1400 F.

After brazing, the assembly was cooled to about 500 F by an air blast (to minimize distortion) before being quenched in hot water and washed to remove flux. (The heating for brazing, followed by the air-blast cooling and the hot-water quench, put the 6061 alloy in a condition that yielded a T4 temper after natural aging for several days.)

After the self-jigging tabs and other extraneous metal had been removed by machining, the brazed chassis assembly was inspected visually. Parts were held within 0.015-in. total tolerance of warp over the 10-in. dimension, and angularity of 1° in 3 in. Fillet radii were held within 0.030 to 0.060 in. at junctures of two parts and within 0.030 to 0.090 in. at junctures of three parts. Fluorescent-dye or radiographic inspection was used in special cases. The rejection rate for this chassis was only 2% from all causes.

Furnace Brazing

Brazing in an atmosphere furnace is a high-production process that requires minimum training and skill of operators. Production rates can be considerably higher, and costs can be lower, than for torch brazing. Aircraft hot air ducts are furnace brazed in as little as one twentieth of the time required to torch braze similar parts. Mass-production assemblies, such as refrigerator evaporators, are brazed at about 500 pieces per hour in continuous furnaces.

Equipment. Heating methods for furnace brazing include electrical heating elements, direct combustion tubes and radiant tubes. Direct combustion furnaces are inexpensive, but the furnace gases may cause undesirable metallurgical effects during brazing of the heat treatable alloys — for example, the 6*xxx* series. Furnaces are generally refractory lined, although such linings become saturated with flux components. Heat-resistant steels, which are normally not recommended because of flux attack, are satisfactory for furnace linings if kept clean, and particularly if aluminum coated.

Whatever the type of furnace, the temperature in the brazing zone must be uniform within ±10 F, and preferably within ±5 F. Circulation of atmosphere, preferably with appropriate baffles, is required, to prevent local heat variations and to obtain the maximum rate of temperature rise.

Technique. Flux slurry may be applied to the parts by dipping, brushing or spraying. Tap, distilled or deionized water can serve as a vehicle; tap water should be free of heavy metals, because these can cause subsequent corrosion. Because hydrogen may be evolved when wet flux is heated on aluminum parts, closed assemblies must be vented. Gas generation can be reduced by drying the flux on the part prior to brazing. Mixing the flux with alcohol instead of water will speed the drying, but the explosive fumes from the alcohol must be dissipated.

Ambient air or chemically inert gas is normally used as the furnace atmosphere. A dry atmosphere (dew point of −40 F) consisting of the products of combustion of fuel can sometimes reduce the amount of flux needed. For brazing aluminum to other metals, an inert, dry atmosphere is particularly beneficial.

Continuous furnace brazing requires furnaces divided into several progressive heating zones to improve heating rate and joint quality and to reduce warpage. A furnace cycle of 15 min or less is desirable. In automated operations, the brazing zone usually requires a travel time of 2 to 3 min for assemblies of moderate size. Because the flux loses its activity in about 30 min, aluminum assemblies large enough and heavy enough to require heating times exceeding this limit should not be furnace brazed.

Beyond the heating portion of the furnace, from 1 to 5 min of conveyor travel should be in an unheated zone to allow the filler metal to solidify. Directly following should be an air blast, a hot-water spray (180 to 212 F), or a boiling-water quench, which begins the

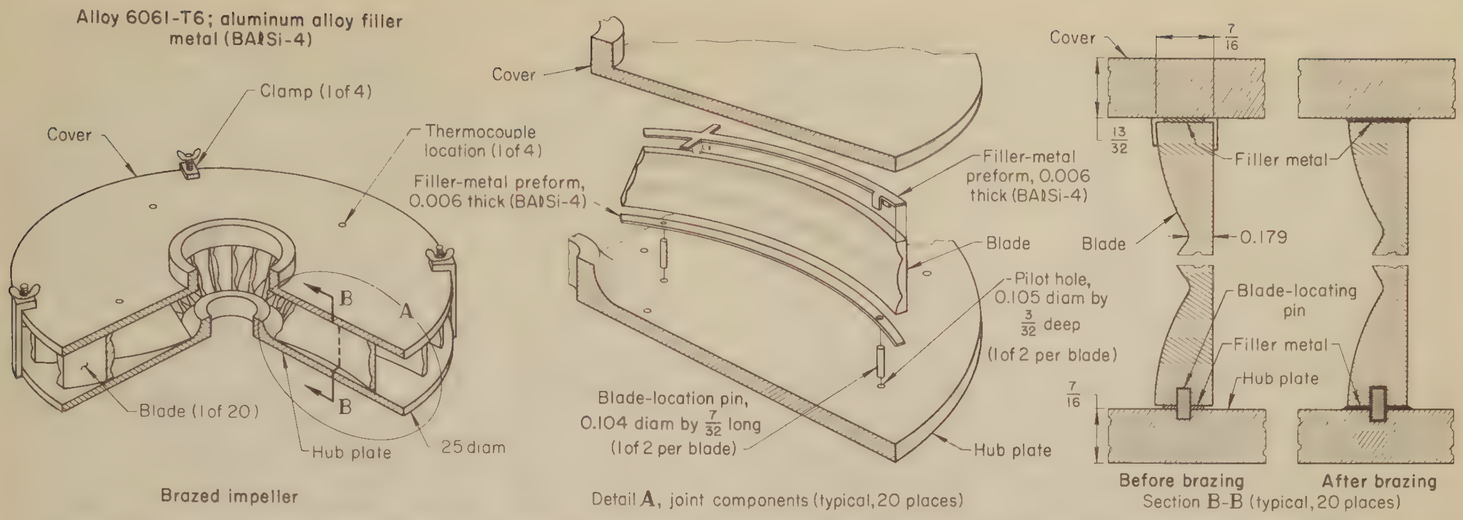

Fig. 10. Furnace brazed impeller assembly, showing the locating pins used to hold the blades in position during brazing (Example 633)

flux-removal process. For the heat treatable alloys, a water quench after brazing will permit improvement in the mechanical properties, especially if the parts are subsequently given an aging treatment.

Batch furnaces are also used for brazing aluminum alloys, as described in the following example.

Example 633. Use of Furnace Brazing To Join an Impeller Assembly (Fig. 10)

Impellers like the one shown in Fig. 10 were used in radial-flow turbo-compressors to increase the recoverable energy content of the gas passing through the compressor. Speeds of various models of impellers ranged from 3000 to 30,000 rpm. More than 80 different sizes of impellers were made. Aluminum was used for impellers that, depending on size and speed, were to run at temperatures up to about 400 F.

The casting of impellers, which was done for some other applications, would have been expensive because of the large investment required for a multiplicity of patterns, the need to make new patterns for design changes and to store the old patterns for replacement orders, the high cost of developing the casting techniques, and expensive inspection requirements.

Brazed impellers were found to be easily manufactured with a large saving in capital cost. The initial capital outlay for producing 80 different sizes of brazed impellers was about 5% of the investment that would have been required for production of the impellers as castings. Design changes were made easily without the need to change equipment. A standard hub plate and cover were used for a number of impeller sizes; only the blade size was changed. Manufacturing cost (exclusive of savings in initial investment) was 1% lower than for casting. Inspection was easier, and the rejection rate of brazed impellers was only one-fourth that of cast impellers. In addition, brazed impellers were salvageable.

Aluminum alloy 6061-T6 plate was selected for the parts of the assembly because of its strength, brazeability and availability. Although brazing destroyed the T6 temper and it was necessary to reheat treat after brazing, the plate was purchased in this temper to avoid possible mixup with other 6061-T6 plate used in the plant, and there was no cost premium for the temper. Blades were cut from a cylinder made by curving the plate on a three-roll former, gas metal-arc welding the longitudinal seam, and stress relieving. The blades were then finish machined to size and shape, and holes for locating pins were drilled on one edge.

The blades, the hub plate (machined and stress relieved), and the cover, together with 0.006-in.-thick BAlSi-4 filler-metal preforms, were cleaned in the following sequence of operations.

1 Immerse in emulsion cleaner at 150 F. The emulsion was a mixture (2 to 3 oz per gallon of water) of alkaline salts combining complex phosphates and sulfates with anionic surface-active agents of the aryl-alkyl sulfonic type.
2 Rinse in cold running water.
3 Immerse in alkaline etching cleaner solution (2 to 3 oz per gallon of water) at 150 to 160 F.
4 Rinse in cold running water.
5 Immerse in nitric acid solution (30 to 40% by weight) at room temperature until all stains or smudges are removed.
6 Rinse in cold running water.
7 Rinse in hot running water.
8 Dry with air blast.

The impeller components and filler-metal preforms were assembled in a clean, air-conditioned room. The hub plate was placed on a rigid baseplate fixture made of type 316 stainless steel. Flux was mixed within 4 hr prior to being used, from 3 parts by volume of a proprietary powder (aluminum fluorides and chlorides) to 1 part of clean water. Aluminum blade-locating pins were inserted in the hub plate and covered with flux. The lower filler-metal preforms were fluxed on both surfaces and put in position over the pins. The blades were fluxed and put in position (located by the pins). The upper filler-metal preform strips were fluxed and placed on the blades.

Tabs were bent down over the blades to hold the filler-metal strips in position. Flux was brushed onto the joint side of the cover. The cover was placed in position over the blades, concentric with the hub plate, and held there by four locating clamps fastened to the cover at 90° intervals and extending down to the bottom of the outside edge of the hub plate.

The cover had been drilled with four ⅛-in.-deep holes on the top surface to accommodate thermocouple beads. For small assemblies, only the holes at the front and back positions during brazing were used. For large assemblies, the holes at the side positions in the furnace also had thermocouple beads peened into them. Care was taken to avoid pickup of foreign metal when making the thermocouple joints and also to avoid contaminating the thermocouple wires with flux.

A box-type furnace, electrically heated on all interior surfaces, was used. The assembly was placed in the furnace, which had been preheated to 1200 F (120 to 130 F above the brazing temperature), and the temperature of the assembly was checked with the thermocouples at regular intervals. When any thermocouple reading was within 50 F of the brazing temperature of 1070 to 1080 F, readings were taken every minute. When the assembly reached brazing temperature, the furnace was opened, and the assembly was removed to cool in air to room temperature. The brazed assembly was washed in hot water to remove flux and then cleaned by the same procedure as used before brazing.

After cleaning, the impeller was solution heat treated, quenched and aged to regain the T6 temper and again was given the same sequence of cleaning operations as before, to remove the slight surface oxidation that formed during heat treatment.

Final inspection included visual examination, dye-penetrant inspection and a hardness check. In addition, the brazed assemblies were inspected for deformation and brazing failure after the impeller was test run 20% over design speed for two minutes in vacuum. Assemblies that showed porosity in a brazed joint were salvaged by recleaning, refluxing, positioning small clips of additional filler metal where needed, and rebrazing. If cracks were found in a joint, the hub plate and cover were salvaged for reuse by cutting apart the assembly. (The used blades were discarded.)

Fluxless Vacuum Brazing

Furnace brazing in a vacuum with the use of no flux offers several advantages. The possibility of flux inclusions is eliminated. Blind cavities, tortuous paths, and small passageways can be designed into the assembly without regard to flux removal or entrapment after brazing. Fluxless brazing also eliminates the cost of flux and its application, the need for cleaning the assembly after brazing, and potential corrosion of equipment and pollution of air and water by flux residues or flux reaction products.

With correct techniques, alloys of the 1*xxx*, 3*xxx*, 5*xxx*, 6*xxx* and 7*xxx* series can be vacuum brazed using X3 and X5 brazing sheets, which are clad with X4003 filler metal. (When additional filler metal is required, X4003 in wire and sheet form also can be introduced.) The joint designs used for brazing with flux can be used for fluxless vacuum brazing.

Equipment. Cold-wall vacuum furnaces with electrical-resistance radiant heaters are recommended for aluminum vacuum brazing. Both batch-type and semicontinuous furnaces are used. The vacuum pumping system should be capable of evacuating a conditioned chamber to a moderate vacuum (about 10^{-5} torr) in 5 min. For most applications, rectangular chambers made of hot rolled steel are suitable. The temperature distribution within the work

Table 5. Typical Conditions for Oxyacetylene and Oxy-Hydrogen Torch Brazing of Aluminum Alloys

Metal thickness, in.	Oxyacetylene brazing: Orifice diameter, in.	Oxygen pressure, psi	Acetylene pressure, psi	Oxy-hydrogen brazing: Orifice diameter, in.	Oxygen pressure, psi	Hydrogen pressure, psi

0.125	0.085	2.0	4	0.115	1.5	3

being brazed should be reasonably uniform, ideally within ±5 F. For many applications, wider ranges are used.

Technique. Components are cleaned, usually by vapor degreasing with a common solvent such as perchlorethylene (ordinarily, chemical cleaning is not required), assembled, and clamped in a suitable fixture made of thin stainless steel sheet. The use of dry cotton gloves is recommended for assembling by hand. Heating of the assembly is started simultaneously with pumpdown of batch-type furnaces. Average time for heating to brazing temperature is about 15 min. The assembly is then held at brazing temperature (see optimum brazing ranges, Table 3) for about 1 min. After backfilling the chamber with chemically inert gas, the assembly is removed at approximately 1000 F. Heat treatable alloys can then be quenched; non-heat-treatable alloys are air cooled. The clean, dry brazed assembly is ready for use or further processing as soon as it is cool.

Torch Brazing

Torch brazing is used for either manual or automatic fabrication, and for repair operations. The uses of torch brazing range from rather simple tube-to-tube joints to more complex and mechanized assemblies. Some of the more common commercial applications are tubular joints in refrigerator coils, miter joints in extruded window frames, and joints between electric heating elements and structures.

Equipment. Oxyacetylene, oxy-hydrogen and oxy-natural gas are employed commercially for torch brazing. It is possible also to use gasoline blowtorches, and all types of gas burners.

Torch brazing is similar to gas welding, in that the heat to effect the joint is applied locally. The torch-tip sizes used are also similar to those for gas welding. The choice of tip size and gas pressures depends on the thickness of the parts and should be determined by trial, using the values in Table 5 as starting points.

With the generally employed fillers, BAlSi-3 (alloy 4145) and BAlSi-4 (alloy 4047), close temperature control is needed, especially for torch brazing of alloys having low solidus (wrought alloys 5052, 6053, 6061 and 7005, and the casting alloys listed in Table 1). Since aluminum alloys show no color when hot, even melting without a color change, it is necessary to have some means for determining when the parts are reaching brazing temperature. The flux used should be one that melts at a slightly lower temperature than the filler metal and thus serves as a temperature indicator. Aligning jigs should be insulated to avoid excessive heat conduction.

Technique. After the components of an assembly to be torch brazed have been suitably cleaned, the joint areas and the filler metal are painted with a slurry of brazing flux, and the components assembled and (if required) jigged. The assembly is then brazed by directing a soft, slightly reducing flame over the entire joint area. The filler metal can be preplaced, or it can be face fed (flowed into the joint when touched against the heated work). The brazed joint should have a smooth fillet, usually requiring little or no finishing. All flux should be removed.

Specialized Brazing Processes

The various processes described in this section are not currently in wide use. For some of these processes, the basic art, knowledge and materials are available, but the applications to date are meager. For others, the technology is not fully developed.

Modifications of Dip Brazing. In one modification of dip brazing, mixtures of filler-metal powder and one of the active components of the flux, such as a fluoride, are applied to the areas to be brazed and are dried, and then the assembly is dipped into a less-active molten flux vehicle.

Another modification is useful when, because of joint design, it is desirable to supply filler metal from a molten bath. This is done in either of two ways: (*a*) assemblies coated with flux (by spraying or dipping) and thoroughly dried are placed into the molten filler metal; or (*b*) the assembly is dipped into a molten flux bath and then dipped into the molten filler metal. In either method, the molten filler metal flows into the capillary spaces at the joints to effect a braze.

Resistance brazing of aluminum alloys most often involves joining of small parts: making connections in electric motor windings is a typical application. Usually, the work is clamped for heating between two carbon blocks held in a tong arrangement. For some jobs, it is clamped in a resistance welding machine.

Alloy Brazing. This fluxless process achieves a braze by first heating the joint area with an interposed shim to form a liquid phase, then extruding this liquid along with surface oxides from the joint cross section. Because of rate of alloying, fluidity, melting temperature, and availability as foil, the preferred shim material is copper. The extreme brittleness of the aluminum-copper intermetallic compounds is no deterrent, because the compounds are entirely displaced by extrusion.

Many types of heating are used for alloy brazing; resistance heating is commonest. Clamping pressure between the carbon blocks is generally 1200 to 2000 psi, based on the overlap area. Current densities of 2500 to 4000 amp per square inch with an operating potential of 9 to 13 volts are satisfactory.

This process is used in the electrical industry, because the electrical conductivity of the brazed joints is essentially the same as the parent aluminum conductor, and the process is low in cost. In addition to simple overlap and butt joints, multiple-ply overlap, thin-to-thick, and round-to-flat joints have been brazed. The simple, inexpensive, fluxless features also make this process attractive for brazing narrow sheet and plate members, butt joining round and square aluminum rod, and sealing the ends of thin-wall tubing. Alloys such as EC, 1060, 1100 and 3003, with solidus temperatures considerably above 1018 F (aluminum-copper eutectic temperature), are the most readily brazed. The 5*xxx* and 6*xxx* alloys with lower solidus temperatures can be brazed if close temperature control is provided.

Motion brazing includes both vibration brazing and flow brazing. As might be expected, vibration of low or ultrasonic frequency has a pronounced beneficial effect in brazing aluminum, particularly when brazing sheet is used. Brazed joints can be made with brazing-sheet parts in the absence of flux and in air. The brazing-sheet surfaces are held together at a temperature preferably above the liquidus of the brazing alloy. A relative movement between the brazing sheets displaces the oxide film on the semiliquid contact surfaces.

In flow brazing, simple joints can be brazed between brazing sheets or even plain aluminum parts. The part to be brazed or the molten filler metal is moved rapidly with respect to the other, causing a mechanical removal of oxide film and the mating of liquid-liquid or solid-liquid interfaces. For simple shapes, this can be done in air; for more difficult shapes, in an inert gas. No flux is used. Vibration is helpful. The total time must be short.

The motion brazing concept has certain obvious limitations. Parts are restricted to rather elementary structures because of the requirements of directional vibration, rate and type of motion, supply of premelted filler alloy to the joint, shape of part, precleaning, and other complicating factors.

Brazing to Other Metals

Aluminum can be brazed to many other metals. In specific applications, painting or other suitable coating may be required after brazing, to minimize subsequent galvanic corrosion of the joint area. Stresses from nonuniform expansion must also be considered.

Aluminum to Ferrous Alloys. Steel should be protected from oxidation during preheating and brazing to aluminum. In dip brazing, oxidation can be prevented by dipping unheated

parts into molten flux, but this procedure has limited application because it is likely to cause warping and misalignment of the components.

Plated or coated steel can be brazed to aluminum more readily than can bare steel. Copper, nickel or zinc electroplates and aluminum, silver, tin or hot dip zinc coatings are used to promote wetting of the steel and to minimize formation of brittle aluminum-iron constituents, thus producing a more ductile joint.

The furnace brazing of plated steel liners or sleeves in aluminum alloy cylinder blocks, as well as steel valve seats in aluminum alloy cylinder heads, has been done experimentally.

Aluminum-coated steels can be torch brazed readily to aluminum, using aluminum filler metals and fluxes. The procedure is the same as in brazing aluminum to aluminum except that preheating should be rapid and brazing time must be minimized, in order to avoid the formation of brittle aluminum-iron phases at the interface. Tube-to-tube joints, with a nominal clearance of about 0.010 in., and laps varying from 0.50 to 2.50 in., have shown shear strengths of 10,000 to 15,000 psi.

In certain complex applications, a multiple-step joining procedure must be employed to permit flux removal. For instance, a section of steel tube was hot dip coated with aluminum at one end, and the aluminum-coated end was dip brazed to a section of aluminum tube. After thoroughly cleaning the brazed subassembly to remove residual brazing flux, the aluminum tube portion was welded to an aluminum container that had been furnace brazed and cleaned in separate operations. The completed assembly was vacuum tight.

Aluminum to Copper. It is difficult to braze aluminum to copper, because of the low melting temperature (1018 F) of the aluminum-copper eutectic and its extreme brittleness. By heating and cooling rapidly, however, reasonably ductile joints are made for applications such as copper inserts in aluminum castings. The usual filler metals and fluxes for brazing aluminum to aluminum can be used, or the silver alloy filler metals BAg-1 and BAg-1a can be used if heating and cooling are rapid (to minimize diffusion). Pretinning the copper surfaces with solder or silver alloy filler metal improves wetting and permits shorter time at brazing temperature. A more practical way to braze aluminum to copper is to braze one end of a short length of aluminum-coated steel tube to the aluminum, and then silver braze the other end of the tube to the copper.

Aluminum to Other Nonferrous Metals. Aluminum-silicon filler metals are unsuitable for brazing aluminum to uncoated titanium because of the formation of brittle intermetallic compounds, but titanium can be hot dip coated with aluminum, after which it can be brazed to aluminum with the usual aluminum filler metals.

Under correct conditions, nickel and nickel alloys are no more difficult to braze to aluminum than are ferrous alloys. They can be brazed directly or precoated with aluminum. Although Monel alloys can be wetted directly, brazed joints are likely to be brittle, and Monel alloys are thus preferably precoated with aluminum.

Beryllium can be wetted directly by aluminum brazing alloys. Magnesium alloys can be brazed to aluminum, but the brazed joints have limited usefulness because of the extremely brittle aluminum-magnesium phases that form at the interface.

Table 6. Solutions for Removing Brazing Flux From Aluminum Parts

Type of solution	Concentration: Amount	Concentration: Component(a)	Operating temperature	Procedure(b)
Nitric acid	5 gal 34 gal	58 to 62% HNO_3 Water	Room	Immerse for 10-20 min; rinse in hot or cold water(c)
Nitric-hydrofluoric acid	4 gal 1 qt 36 gal	58 to 62% HNO_3 48% HF (1.15 sp gr) Water	Room	Immerse for 10-15 min; rinse in cold water, rinse in hot water; dry(d)
Hydrofluoric acid	10 pt 40 gal	48% HF Water	Room	Immerse for 5-10 min; rinse in cold water; dip in nitric acid solution shown at top of table; rinse in hot or cold water(d)
Phosphoric acid – chromium trioxide	1½ gal 7¼ lb 40 gal	85% H_3PO_4 CrO_3 Water	180 F	Immerse for 10-15 min; rinse in hot or cold water(e)
Nitric acid – sodium dichromate	4½ gal 32 lb 36 gal	58 to 62% HNO_3 $Na_2Cr_2O_7 \cdot 2H_2O$ Water	140 F	Immerse for 5-30 min; rinse in hot water(f)

(a) All compositions in weight per cent. (b) Before using any of the above solutions, it is recommended that the assembly first be immersed in boiling water to remove the major portion of the flux. (c) Flux contamination in acid should not exceed 5 grams per liter of chloride expressed as sodium chloride. Solution is not recommended for use on base metals less than 0.020 in. thick.

(d) Flux contamination in acid should not exceed 3 grams per liter of chloride expressed as hydrochloric acid. Solution is aggressive, and not recommended for base metals less than 0.020 in. thick. (e) Tolerance for flux contamination is in excess of 100 grams per liter, and permissible limit will probably be governed by cleaning ability. If large pockets of flux are present, solution will promote intergranular attack at the pocket. Recommended for final cleaning of thin-gage parts, when most of the flux can be removed easily in water. (f) Exceptionally high flux tolerance. Recommended for cleaning thin-gage assemblies, if adequacy of water cleaning is doubtful. License required.

Flux Removal

Fluxes used in brazing aluminum alloys can cause corrosion if allowed to remain on the parts. It is therefore essential to clean joints after brazing. A thorough water rinse followed by a chemical treatment is the most effective means of complete flux removal.

As much flux as possible should be removed by immersing the parts in an overflowing bath of boiling water just after the filler metal has solidified. If such a quench produces distortion, the parts should be allowed to cool in air before immersion, to decrease the thermal shock. When both sides of a brazed joint are accessible, scrubbing with a fiber brush in boiling water will remove most of the flux. For parts too large for water baths, the joints should be scrubbed with hot water and rinsed with cold water. A pressure spray washer may be the best first step. A steam jet is also effective in opening passages plugged by flux.

Any of several acid solutions (Table 6) will remove any flux remaining after washing. The choice depends largely on the thickness of the brazed parts, accessibility of fluxed areas and the adequacy of flux removal in the initial water treatment. A pitting or intergranular type of attack on parts can result as chlorides from the flux build up in the acid solution. Some solutions have a greater tolerance for these chlorides than others before parts are attacked. The degree of flux contamination tolerable for the five typical flux-removal solutions listed in Table 6 are given in the footnotes of the table.

The two chromium-containing solutions in Table 6 have the greater tolerance for chlorides and are preferred for thin-wall assemblies. In areas where disposal of chromates presents a problem, the nitric acid solution can be used if inhibitors such as 1% thiourea or triethanolamine salt of sulfolaurylalkylbenzoate are added. As a corrosion inhibitor, about 0.5% sodium or potassium dichromate is sometimes added to the final rinse water.

Agitation and turbulence improve the efficiency of any flux-removal treatment. Ultrasonic cleaning is effective for cleaning inaccessible areas, decreases the immersion time and reduces the possibility of attack on the aluminum.

Checking for complete flux removal should be a routine inspection procedure. To detect the presence of flux, a few drops of distilled water are put on the surface to be tested and left there for a few seconds. The water is then picked off with an eyedropper and placed in an acidified solution of 5% silver nitrate. If the solution stays clear, the metal is clean. If a white precipitate clouds the solution, flux was present on the surface. Flux-removal procedures must then be repeated until the brazed assembly tests clean. Complete removal of the flux is essential, because it is corrosive to aluminum in the presence of moisture.

Postbraze Heat Treatment

Brazing temperatures exceed the solution heat treatment temperatures used for aluminum alloys, and heat treatable aluminum alloys can attain full strength by aging after being quenched from the brazing temperature. After brazing of alloy 7005, a normal air quench for small parts of 5 F per second, or even a cooling rate as slow as 1 F per second, is adequate for precipitation hardening to occur at room temperature. Except as dictated by distortion problems, postbraze quenching and aging treatments are the same as for the base alloy. Typical treatment for artificially aging a heat

treatable alloy brazed assembly is 16 to 20 hr at 320 F, or 6 to 10 hr at 350 F.

Finishing

Because of the smooth, uniform fillets resulting from the brazing operation, little if any mechanical treatment is required before final finishing. If flux has been completely removed (or if fluxless brazing has been used), all chemical and electrochemical finishing treatments are effective when the brazed structures are aluminum throughout. Because of the high silicon content of the filler-metal fillets, any treatment that thickens the oxide or preferentially etches aluminum, leaving a residue of silicon, may cause the fillets to be a darker color than the remainder of the product.

Brazing fluxes containing chlorides of zinc or other heavy metals will deposit that metal on the surface of aluminum parts. These fluxes, as well as fluxes that cause severe etching of aluminum, should be avoided for highest quality in chemical finishing.

Mechanical Properties

At least a part of the base metal is heated above its annealing temperature during the brazing cycle. Torch brazing may anneal only a small region near the joint, whereas dip or furnace brazing anneals the entire assembly. Unless the completed part is quenched and aged, heat treated, or cold worked, the metal that was heated will have mechanical properties typical of the annealed alloy.

When the alloy is heat treatable, improved strength can be imparted by quenching directly from the brazing furnace or dip pot, then artificially or naturally aging according to regular procedures for the alloy involved. Another alternative is solution heat treating and aging as separate operations after brazing. Heat treating is not always possible, because the rapid quenching required for most heat treatable alloys can cause distortion. Alloy 7005 will age harden at room temperature to T6 properties after normal air cooling (1 to 2 F per sec) from brazing temperature. Table 7 lists typical properties of alloy 7005 air cooled from brazing temperature.

Table 7. Tensile Properties of 0.063-In.-Thick Alloy 7005 Heated as in Brazing (a)

Room-temperature aging treatment	Tensile strength, psi	Yield strength, psi	Elongation in 2 in., %
None	28,000	12,000	26
3 days	42,000	21,000	22
1 week	45,000	24,000	22
1 month	49,000	27,000	21
3 months	52,000	30,000	21
6 months	54,000	32,000	21
T63(b)	52,000	44,000	13

(a) Heated 10 min at 1090 F, air cooled, aged as designated. (b) Artificially aged (after solution heat treatment).

Resistance to Corrosion

The aluminum alloys best suited for brazing are also among those most resistant to corrosion. Corrosion resistance of aluminum alloys generally is unimpaired by brazing if a fluxless brazing process is used or if flux is completely removed after brazing. If flux removal is inadequate, the presence of moisture can lead to interdendritic attack on the filler metal at joint faces and to intergranular attack on the base metal.

When two aluminum alloys are brazed together, exposure to salt water or some other electrolyte may result in attack on the more anodic alloy. This condition is aggravated if the anodic part is relatively small compared with the other piece. It helps, therefore, to have the anodic aluminum alloy the larger of the two members.

Torch brazed alclad 3003 and alclad 3004 show excellent resistance to corrosion. Furnace or dip brazing, however, causes a certain amount of diffusion of the clad surface, which limits application of these methods with conventional alclad products. A brazing sheet with filler metal on one side and alclad with a special alloy on the other (see Fig. 2d) performs well in furnace or dip brazing.

Commercial filler metals of the aluminum-silicon type have high resistance to corrosion, comparable to that of the base metals usually brazed. Filler metals containing substantial amounts of copper or zinc are less resistant to corrosion, but they are usually adequate, except for service in severe environments.

Joints brazed with aluminum-silicon filler metals — BAlSi-2 (alloy 4343), BAlSi-4 (alloy 4047) and BAlSi-5 (alloy 4045) — all show a potential of −0.82 volt with respect to a 0.1*N* calomel reference electrode in an aqueous solution of 53 grams-per-liter of sodium chloride and 3 grams-per-liter of hydrogen peroxide. This potential is barely cathodic to the commonly brazed base metals, for which the value is −0.83 volt for 1100, 3003, 6061 and 6063. Therefore, there is little electrolytic action in assemblies of these base metals brazed with the usual filler metals.

The potential of joints brazed with filler metal BAlSi-3 (alloy 4145), which contains copper in addition to aluminum and silicon, depends on the cooling rate after brazing. For slow cooling, these joints have about the same potential as joints brazed with the aluminum-silicon filler metals (−0.82 volt). If the cooling is rapid enough to retain a substantial amount of copper in solid solution, the potential will be lower; a potential of −0.73 volt has been found for T-joints in 0.064-in. sheet brazed with BAlSi-3 filler metal and rapidly cooled.

Although considerable undissolved silicon-containing constituent is evident in brazed joints, it polarizes strongly (except in acid chloride environments) and has little influence on the potential of the brazed joint and its corrosion resistance.

Table 8 shows the results of long-time exposure in a highly corrosive environment of various sheet alloys that were furnace brazed with filler metal BAlSi-3 (alloy 4145). The good performance can be considered typical of a variety of brazing combinations.

Table 8. Results of Microscopic Examination of Furnace Brazed Specimens Exposed Two Years to 3.5% Sodium Chloride Intermittent Spray (a)

Sheet alloy	Filler metal(b)	Sheet (base metal): Type of attack(c)	Sheet: Depth of attack, in.: Maximum	Sheet: Depth of attack, in.: Average	Joint (filler metal): Type of attack(c)	Joint: Depth of attack, in.: Maximum	Joint: Depth of attack, in.: Average
3003	4145	P	0.0098	0.0022	P	0.0014	0.0011
5052	4145	P	0.0182	0.0042	P	0.0042	0.0014
6053	4145	P + I	0.0126	0.0028	P	0.0012	0.0008
6061	4145	P + SI	0.0126	0.0033	P	0.0042	0.0014

(a) Specimens were small inverted T-joints of 0.064-in. sheet. (b) Filler metal 4145 corresponds to BAlSi-3. (c) P = pitting attack; I = intergranular attack; SI = slight intergranular attack.

Safety

Many of the safety considerations discussed in the articles on brazing processes (pages 593 to 660) are applicable to the brazing of aluminum alloys by the same processes. The principal hazard in brazing aluminum alloys that is not present in brazing steel or copper alloys arises from the use of molten fluorine-containing fluxes in dip brazing. Toxic effects may be produced by the inhalation of fumes from the fluorine compounds, and exhaust facilities are required for dip brazing. Furnace brazing with fluorine-bearing fluxes requires regular exhaust of the fumes generated, to prevent attack on exposed metals; the air changes necessary for this reason are also adequate from the standpoint of health protection.

Brazing of Copper and Copper Alloys

*By the ASM Committee on Welding and Brazing of Copper and Copper Alloys**

MOST commercial coppers and copper alloys can be brazed satisfactorily, using one or more of the conventional brazing processes (furnace, torch, induction, resistance, and dip brazing).

Brazeability

The brazeability of coppers and copper alloys is generally rated from good to excellent. With some of the brazeable alloys, however, specific difficulties may be encountered. For example, some lead-containing alloys can form a dross that interferes with wetting, and several tin-containing alloys, if not stress relieved before brazing, may crack when subjected to rapid localized heating. The brazing characteristics of the coppers and the principal groups of copper alloys are considered in the following paragraphs. Nominal compositions of commercial coppers and copper alloys are tabulated on pages 338 and 476 in this volume.

Coppers. Included in this group are electrolytic tough pitch (ETP), phosphorus-deoxidized (DLP and DHP), and oxygen-free (OF) coppers, together with coppers containing not more than about 1% of an additive element, such as silver (STP), zirconium, chromium, lead, selenium, tellurium or sulfur.

Electrolytic tough pitch copper is subject to embrittlement when heated in a hydrogen-containing atmosphere. The rate of diffusion of hydrogen in heated copper is high, and at temperatures above 900 F even relatively small amounts of hydrogen result in embrittlement and internal cracking due to the reduction of copper oxide by hydrogen and the formation of water vapor within the solid metal. Consequently, although electrolytic tough pitch copper is generally rated as having good to excellent brazeability, it should not be brazed in a furnace that contains hydrogen or a hydrogen-containing prepared atmosphere such as dissociated ammonia, or in an exothermic-base or endothermic-base atmosphere. Heating by open flame or by torch also may result in hydrogen diffusion and embrittlement.

Phosphorus-deoxidized and oxygen-free coppers can be brazed in hydrogen-containing atmospheres without risk of embrittlement and, provided the self-fluxing copper-phosphorus or copper-silver-phosphorus filler metals (BCuP series) are used, can be brazed without flux. The use of flux is normally required, however, when the silver alloy filler metals that contain additives such as zinc, cadmium or lithium (BAg series) are used to braze these coppers or to braze these coppers to copper alloys or other metals.

*For committee list, see page 337. More than half of the examples presented in this article were contributed by members of other Metals Handbook welding and brazing committees.

The coppers that contain small additions of silver, lead, tellurium, selenium or sulfur (generally no more than 1%) are readily brazed with the self-fluxing BCuP filler metals, but wetting action is improved when a flux is used and when a sliding motion between components is provided while the filler metal is molten. Coppers that contain beryllium, chromium or zirconium are precipitation hardenable; brazing these coppers in the aged condition impairs their mechanical properties. However, when it is possible to combine brazing with solution heat treatment, properties can be at least partly restored by a subsequent aging treatment.

Beryllium copper can be brazed and solution heat treated by heating to 1450 F, followed by rapid quenching. Subsequent aging at about 600 F will develop maximum hardness. When the sections to be brazed are thin and can be cooled very rapidly, it is often possible to braze solution heat treated beryllium copper in the temperature range of 1150 to 1200 F, quench rapidly, and age to a hardness that approaches the maximum obtainable. To ensure proper wetting, the joint surfaces of beryllium copper parts should be freshly machined or mechanically abraded before being brazed; to remove the beryllium oxide from joint surfaces, a flux with a high fluoride content should be used.

When chromium and zirconium coppers are brazed at a temperature within the solution treatment range (1800 F, for example), brazing and solution treatment can be combined, provided the parts can be cooled rapidly from the brazing temperature. Brazed parts can then be aged in a subsequent operation to develop desired mechanical properties and electrical conductivity.

Red brasses (copper-zinc alloys that contain up to 20% zinc) are readily brazed with a variety of filler metals. Flux is normally required for best results.

Yellow brasses (copper-zinc alloys that contain 25 to 40% zinc) are readily brazed, but low-melting filler metals should be used, to avoid dezincification of the base metal. Yellow brasses are susceptible to stress-corrosion cracking, particularly in the presence of ammonium compounds. Therefore, they should never be brazed in ammonia-containing atmospheres.

Leaded Brasses. When added to red brass or yellow brass, lead forms a dross on heating that can seriously impair wetting and the flow of filler metal. Consequently, in brazing of leaded brasses, the use of a flux is mandatory, to prevent dross formation in the joint area.

The susceptibility of leaded brasses to hot cracking varies directly with lead content. Therefore, these alloys must be essentially free of residual stress prior to brazing. Heating to the brazing temperature should be slow and uniform, to minimize thermal stressing. Brazing results are poor at a lead content of 3% and become worse as the lead content is increased, because of grain-boundary effects and the brittleness of phases formed in the joint by lead and the filler metal. Alloys containing more than 5% lead should never be brazed.

Tin-containing brasses, which include admiralty brass, naval brass and leaded naval brass, contain up to 1% tin and may contain other alloying elements such as lead, manganese, arsenic, nickel and aluminum. Except for the aluminum-containing alloys, these brasses are readily brazed; they have greater resistance to thermal shock and are less susceptible to hot cracking than the high-lead brasses. For proper wetting, the brasses that contain aluminum require a special flux, such as type 4.

Phosphor Bronzes. These copper-tin alloys contain small amounts of phosphorus, up to about 0.25%, added as a deoxidizer. Although susceptible to hot cracking in the cold worked condition, alloys in this group have good brazeability and are adaptable to brazing with any of the common filler metals that have melting temperatures lower than that of the base metal. The use of a flux is generally preferred. To avoid cracking, parts made from phosphor bronzes should be stress relieved at approximately 375 F before brazing.

Silicon bronzes, which contain up to about 3.25% silicon and are in a highly stressed condition, are susceptible to hot shortness and stress cracking by molten filler metal. To avoid cracking, the alloys should be stress relieved at about 475 F prior to brazing. For best brazing results, joint surfaces should be freshly machined or mechanically cleaned. Silicon bronzes containing aluminum require the use of type 4 flux (see page 686 and Table 2).

Aluminum Bronzes. Because of their aluminum content, which results in the formation of aluminum oxide on the surface, aluminum bronzes are generally considered difficult to braze. However, alloys containing 8% aluminum or less are brazeable, provided type 4 flux is used to dissolve the aluminum oxide. The oxide, which inhibits the flow of filler metal, cannot be reduced in dry hydrogen. Use of the low-melting high-silver filler metals is recommended for these bronzes.

Copper nickels, which may contain from about 10 to 40% nickel, are susceptible both to hot cracking and to stress cracking by molten filler metal. The silver alloy filler metals (BAg series) are preferred for brazing these alloys. In general, the use of filler metals containing phosphorus should be avoided, because the copper nickels are susceptible to the formation of brittle nickel phosphides at the interface, which lowers joint ductility.

Nickel silvers (brasses that contain up to about 20% nickel but that do not contain silver) are highly susceptible to hot cracking and should be stress relieved at about 475 F before being brazed. They have low thermal conductivity and should be heated and cooled slowly and uniformly.

Brazing Dissimilar Alloys. Most of the alloys belonging to any one of the above groups can be brazed to an alloy of another group. However, to achieve compatibility, some compromise may be required in the selection of brazing temperature, filler metal and flux. For example, if a component made of copper is to be brazed to a component made of aluminum bronze, the brazing temperature should be predicated on the lower melting temperature of the bronze rather than on the higher melting temperature of the copper, and a suitable flux should be selected to accommodate the bronze, even though the copper could be brazed satisfactorily without a flux, using a self-fluxing filler metal of the BCuP series.

It is not uncommon for three or more different copper alloys to be brazed together in a single assembly (see Example 636).

Filler Metals

Table 1 presents the nominal compositions, solidus and liquidus temperatures, and electrical conductivities of some filler metals commonly used in brazing of copper and copper alloys, and the joint clearance used with each. The filler metals listed in Table 1 represent four series: copper-zinc (RBCuZn) alloys, copper-phosphorus and copper-silver-phosphorus (BCuP) alloys, silver (BAg) alloys, and gold (BAu) alloys. Omitted from Table 1 are the copper (BCu) filler metals, which, because of their high liquidus temperature (1980 F), are restricted to use with the copper-nickel alloys only. Of the filler metals listed in Table 1, the BCuP and BAg alloys are by far the most widely used in brazing copper and its alloys.

Copper-Zinc (RBCuZn) Filler Metals. Because of their high liquidus temperatures, their limited corrosion resistance, and their sensitivity to overheating, the copper-zinc filler metals are seldom used in brazing copper and copper alloys. Overheating causes the zinc to vaporize and form voids in the joint. In applications where corrosion resistance is not of importance, these filler metals can be used for joining copper, copper nickel, silicon bronze, and phosphor bronze. They are sometimes used in joining copper to steel, stainless steel and nickel alloys. In general, these filler metals require the use of a flux.

Copper-Phosphorus and Copper-Phosphorus-Silver (BCuP) Filler Metals. The BCuP alloys are self-fluxing when used for brazing unalloyed coppers, but the use of a flux is generally recommended when these filler metals are employed in brazing the special coppers and copper alloys. The BCuP filler metals are not used in brazing beryllium copper, because the resulting deposit in the joint is highly porous; in general, they are not suitable for use in brazing copper-nickel alloys containing more than 30% nickel. The BCuP filler metals have good corrosion resistance, but they are severely attacked in sulfur-bearing atmospheres at elevated temperature. Among the advantages of these filler metals are their relatively low cost.

Silver Alloy (BAg) Filler Metals. The silver alloy filler metals listed in Table 1 are suitable for use with all brazeable coppers and copper alloys and most dissimilar-alloy combinations. The lower brazing temperatures indicated in Table 1 for some of the silver alloy filler metals make them particularly well-suited for brazing copper alloys with an appreciable zinc content, such as the yellow brasses, which are subject to dezincification. The corrosion resistance of silver alloy filler metals ranges from good to excellent, although the cadmium-containing silver alloys are avoided when brazing equipment for the dairy, food, and pharmaceutical industries, because of the high toxicity of cadmium. The principal disadvantage of silver alloy filler metals is high cost, but this disadvantage can be largely offset by correct joint design. Flux is generally required for all but the lithium-containing filler metals (BAg-8a and BAg-19), which are self-fluxing in dry, nonoxidizing protective atmospheres by virtue of the ability of lithium to reduce refractory oxides on the base-metal surfaces at brazing temperature.

Gold alloy (BAu) filler metals, such as BAu-4 in Table 1, are high-cost compositions that are generally restricted to applications requiring exceptional corrosion resistance and to highly specialized applications such as joining vacuum-tube components that are hermetically sealed, where the low vapor pressure of gold is advantageous. The high liquidus temperatures of gold alloy filler metals further limit their use to brazing coppers and a few high-melting copper-nickel alloys.

Brazing Fluxes

The four types of fluxes used in brazing of coppers and copper alloys are listed in Table 2. All are marketed as proprietary compositions; there are no standard composition ranges.

Type 3A is a general-purpose, low-temperature flux suitable for use with all copper and copper alloy base metals except those containing substantial amounts of aluminum. The filler metals that are compatible with this flux include most of the copper-phosphorus alloys (with the exception of BCuP-1) and most of the silver alloys (including all those with liquidus temperatures below 1600 F).

Type 3B flux is a modification of type 3A for use at higher temperatures. The active temperature range of type 3B flux is 1350 to 2100 F. This flux can be used for brazing with any of the filler metals listed in Table 1, provided the brazing temperature is above 1350 F.

Type 4 flux is specifically formulated for brazing the aluminum-bearing copper alloys, and has the same working-temperature range as type 3A flux — 1050 to 1600 F. This flux is generally used with the silver alloy filler metals.

Type 5 flux, which has a working-temperature range of 1400 to 2200 F, is most commonly used with the copper-zinc filler metals. It is less active than type 3B flux, but it remains active longer (as required by the longer heating cycles used to braze heavy components), and costs less.

Joint Clearance

Joint clearance is a principal factor in determining the mechanical strength of brazed joints. It is also a factor in eliminating harmful voids in the joint area and in establishing the capillary force required to fill the joint.

Typical diametral joint clearances for use with the filler metals commonly employed in joining copper and copper alloys are given in Table 1. These are clearances at room temperature and are applicable to brazing components of about the same mass made from the same copper or copper alloy. Adjustments may be required for brazing dissimilar metals to compensate for different coefficients of thermal expansion.

Selection of Brazing Process

Often the size and shape of an assembly will suggest a preferred brazing process to the exclusion of other proc-

Table 1. Nominal Compositions, Solidus and Liquidus Temperatures, and Electrical Conductivities of Some Filler Metals Commonly Used in Brazing of Copper and Copper Alloys, and Typical Joint Clearances Used With These Filler Metals

esses. When two or more brazing processes have approximately equal suitability for brazing a given assembly, the quantity of assemblies to be brazed, because of its direct bearing on cost, is likely to be the deciding factor in process selection.

Comparative production rates and labor costs for brazing each of three different assemblies by different brazing processes are given in Table 3. Additional data are presented in the sections of this article that deal with the various brazing processes.

The five sections that comprise the remainder of this article discuss aspects of furnace brazing, torch brazing, induction brazing, resistance brazing, and dip brazing that are specific to the application of the five processes to copper and copper alloys. These sections also present 28 examples of production practice illustrating the use of the processes.

For detailed discussion of equipment and operating conditions that may be generally applicable to the use of the five processes in brazing any metal, the reader is referred to the five articles on pages 593 to 660 in this volume, which deal individually with the different brazing processes.

Furnace Brazing

Furnace brazing is a mass-production process. Its primary advantage is that it can be used to process a large number of assemblies on a batch or continuous basis at low unit cost. Other advantages of furnace brazing are that it can be used to braze a number of joints on the same assembly simultaneously, or to braze a variety of different assemblies simultaneously, and that it provides an enclosed container for atmospheres that can protect assemblies against surface oxidation and other undesirable effects encountered when heating in air.

In all furnace brazing applications, the filler metal must be preplaced before the assembly enters the furnace, and retained in position until brazing and solidification are completed.

Advantages of furnace brazing that are more specifically applicable to the joining of copper and copper alloys relate to the furnace as a source of heat and to the cooling chamber — a necessary adjunct to all brazing furnaces, as a means for cooling assemblies from the brazing temperature to 300 F or below. To a lesser degree, the prepared protective atmospheres that can be used most conveniently in furnace brazing, notably the exothermic-base and endothermic-base atmospheres, constitute another advantage when brazing deoxidized coppers and copper alloys in a furnace.

The rate of heating assemblies in a brazing furnace is low in comparison with the rates normally employed in torch, induction and resistance brazing. Few furnace heating cycles are less than five minutes in duration. For heating copper alloys susceptible to hot cracking, however, the slower, more uniform heating of a furnace is desirable.

In conveyor-type furnaces with multiple-zone heating chambers, the heating rate can be controlled with great accuracy. Depending on furnace capacity and the size of the assemblies to be brazed, the production rate in furnace brazing may equal or exceed that obtainable in induction brazing for the same amount of energy expended (assemblies per kilowatt-hour of input, for example).

The cooling rates that can be obtained in the cooling chambers of brazing furnaces can be closely controlled to ensure slow, uniform cooling. For copper alloys susceptible to hot cracking, the control of cooling rate from the brazing temperature is as important as control of the rate of heating to the brazing temperature.

Limitations. Apart from high initial equipment costs and the floor space required to accommodate a furnace with both a heating chamber and a cooling chamber (the length of the cooling chamber is usually at least three times that of the heating chamber), most of the limitations of furnace brazing are related to the deleterious effects of furnace temperatures and brazing fluxes on furnace muffles and linings, electrical heating elements, rails, trays, conveyor belts and other components. In general, these effects increase in seriousness as the operating temperature of the furnace increases. A furnace used for brazing copper and copper alloys with silver alloy filler metals and operating at a temperature below 1500 F could be expected to require considerably less maintenance, repair, and replacement of components than a similar furnace used to braze carbon steel with copper filler metals and operating at a temperature of 2000 F. The use of flux, required for brazing with most silver alloy filler metals, could offset the advantage of a lower operating temperature, however, by introducing corrosion and corrosive deterioration that are not encountered in a flux-free furnace chamber.

A furnace operating at 1500 F requires idling at elevated temperature when not in use, as does a furnace operating at 2000 F, thereby adding to power costs. Idling prevents thermal cycling that can cause serious damage to furnace brickwork and other components. Lower operating temperatures usually permit the use of lower idling temperatures. However, for furnaces operating with combustible protective atmospheres, the hazard of explosion is greatest when the furnace is operating at temperatures below about 1400 F, and special precautions must be scrupulously observed in this range (see the Appendix on Safe Operation of Brazing Furnaces, which begins on page 614 in this volume).

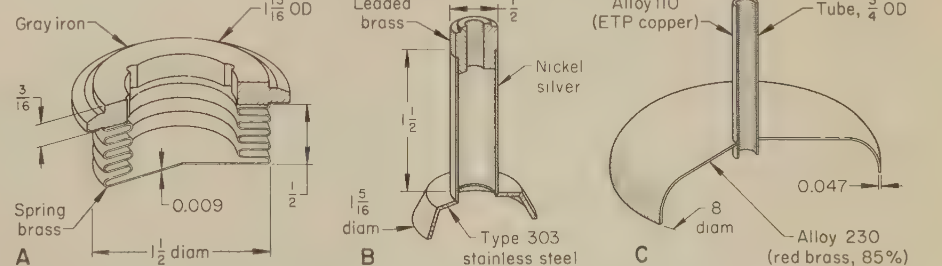
Furnaces. In terms of design and equipment, the furnaces used for brazing copper and copper alloys are essentially the same as those used for brazing steel (see pages 594 to 597 in the article on Furnace Brazing of Steel).

Table 2. Fluxes Used in Brazing of Copper and Copper Alloys

AWS type	Working temperature, F	Ingredients	Available forms	Base metals	Filler metals
3A	1050 to 1600	Boric acid Borates Fluorides Fluoborates Wetting agent	Powder Paste Liquid	All coppers and copper alloys except aluminum bronzes	BCuP and BAg series, except for BCuP-1 and BAg-19
3B	1350 to 2100	Boric acid Borates Fluorides Fluoborates Wetting agent	Powder Paste Liquid	All coppers and copper alloys except aluminum bronzes	All listed in Table 1
4	1050 to 1600	Chlorides Fluorides Borates Wetting agent	Powder Paste	Aluminum bronzes	BAg series (principally)
5	1400 to 2200	Borax Boric acid Borates Wetting agent	Powder Paste Liquid	All coppers and copper alloys except aluminum bronzes	RBCuZn series (principally)

Table 3. Comparison of Production Rates and Direct-Labor Costs for Brazing Three Different Assemblies by Different Processes

Assembly brazed (see drawings below)	Brazing process	Production rate, assemblies per hr	Direct labor: Rate per hour	Direct labor: Cost per assembly
A	Induction	720	$1.44	$0.002
A	Torch (manual)	120(a)	2.40	0.02(a)
B	Furnace	140	2.10	0.015
B	Torch (manual)	60(b)	2.40	0.04(b)
C	Induction	60(b)	1.44	0.024(b)
C	Furnace	12(c)	2.10	0.175(c)



(a) 30 sec for preparation and heating; one assembly at a time. (b) 60 sec for preparation and heating; one assembly at a time. (c) 5 min for preparation and heating; one assembly at a time.

Because of the damaging effects of sulfur and sulfur-bearing compounds on copper and copper alloys, the products of combustion in gas-fired furnaces operating without a muffle must be completely free of all traces of sulfur. Electric furnaces may be operated without a muffle unless damage caused by volatilized flux and flux droppings to brickwork and other furnace components warrants use of a muffle. Muffles may also be used to ensure the purity and to maintain the dew point of a protective atmosphere, particularly when the atmosphere is serving in place of a flux and its effectiveness depends on freedom from contamination. In the following example, which also describes a method for maintaining hole alignment between two components during furnace brazing, a nickel alloy muffle was used in the heating zone of an electric mesh-belt conveyor furnace to contain a purified hydrogen atmosphere.

Example 634. Use of a Nickel Alloy Muffle To Contain a Hydrogen Atmosphere Used in Place of a Flux (Fig. 1)

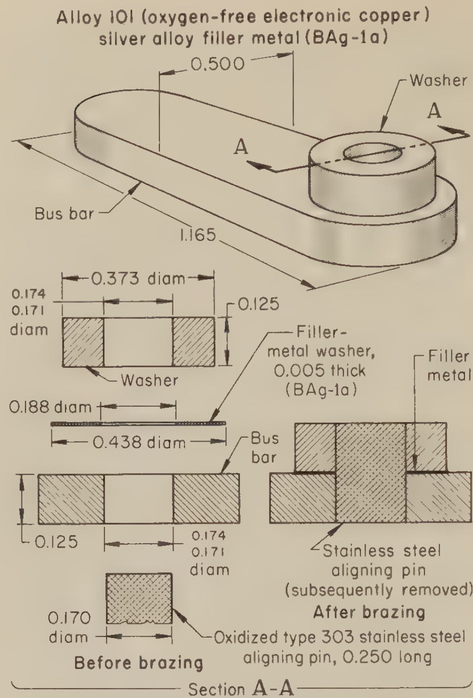
The electrical contact assembly shown in Fig. 1, a component of an aircraft power relay, was brazed in a continuous, electrically heated, mesh-belt conveyor furnace equipped with an Inconel alloy full muffle in the five-zone heating chamber. The muffle was filled with hydrogen supplied from a tank truck and subsequently dried in a palladium diffuser-purifier; the use of a pure, dry hydrogen atmosphere during brazing eliminated need for a brazing flux.

As shown in Fig. 1, the contact assembly was made by brazing a copper washer to a copper bus bar with a preformed 0.005-in.-thick silver (BAg-1a) filler-metal washer preplaced between the copper components. A major difficulty was to maintain hole alignment between the two components during the brazing cycle. This difficulty was overcome by inserting an aligning pin, made of an oxidized type 303 stainless steel, into each assembly. Assembly consisted of positioning the flat filler-metal preform over the hole in the bus bar, placing the copper washer on it, and then pressing the stainless steel pin through the hole. The oxide coating on the stainless pin prevented wetting of the pin by the filler metal; the coating was not reduced by the hydrogen atmosphere at the comparatively low brazing temperature (1260 F).

The assemblies were placed on the furnace conveyor belt and were carried through the five-zone heating chamber in an elapsed time of 9 min; after brazing, they were conveyed through the water-jacketed cooling chamber of the furnace, where they were cooled nearly to room temperature before leaving the furnace.

After brazing, the operator used a small tool similar to an arbor press to remove the pins. The assembly was then ready for the next operation, which consisted of resistance brazing a silver – cadmium oxide contact button to the end of the bus bar.

Visual inspection was used to determine that there was a small concave fillet of filler metal all around the joint. Sample lots were peel tested or sectioned. It was required that the area joined by brazing be not less than 80% of the area of the mating portions of the two components. Additional brazing details are given in the table with Fig. 1.



Conditions for Furnace Brazing

Furnace type	Mesh-belt conveyor(a)
Atmosphere	Hydrogen(b)
Filler metal	BAg-1a preform (see drawing)
Flux	None
Brazing temperature	1260 F
Production rate	350 assemblies per hour(c)
Gas cost	$3 per hour

(a) Five-zone, 17-kw electric furnace, with 4-in. by 4-in. Inconel alloy muffle. (b) Supplied from a tank truck and subsequently dried in a palladium diffuser-purifier before entering the furnace. Nitrogen, supplied from liquid bulk storage, was used for purging. (c) Limited by manual assembly.

Fig. 1. Electrical-contact assembly that was furnace brazed in a hydrogen atmosphere confined by an Inconel alloy muffle (Example 634)

Temperatures for furnace brazing depend primarily on the filler metal used, which in turn is necessarily related to the melting temperature of the base metal and to certain harmful effects, such as dezincification and hot-short cracking, that result from exceeding prescribed temperature limits. The brazing temperature selected is usually at least 50 F higher than the liquidus temperature of the filler metal and even higher brazing temperatures may be employed to promote fluidity or to achieve other desired results (as, for example, combining brazing and solution heat treatment in the same furnace operation). Some filler metals can be used at a temperature below the liquidus (BCuP-3, with a liquidus of 1485 F, and BCuP-5, with a liquidus of 1475 F, flow freely and make good joints at 1300 F; BCuP-5 was used at 1325 F in Example 599). In the next example, furnace brazing was done at 75 F below the liquidus of the filler metal (a silver-containing BCuP alloy), without using a protective atmosphere.

Example 635. Brazing at 75 F Below the Liquidus of the Filler Metal, Without Protective Atmosphere (Fig. 2)

The contact-arm assembly shown in Fig. 2 was a component of a line-voltage thermostat. The two contacts were made of fine silver and, when brazed to the copper arm, required a highly conductive joint to accommodate high service currents without overheating.

This application of furnace brazing was unusual because neither a flux nor a protective atmosphere was used and the brazing temperature was considerably below the liquidus of the filler metal. The copper-silver-phosphorus (BCuP-5) filler metal was self-fluxing on both copper and silver, and its unusually wide temperature range between solidus and liquidus (1190 to 1475 F) permitted brazing at a temperature below the liquidus. The assembly was brazed at 1400 F, 75 F below the liquidus temperature, in a mesh-belt conveyor furnace at a production rate of 377 assemblies per hour.

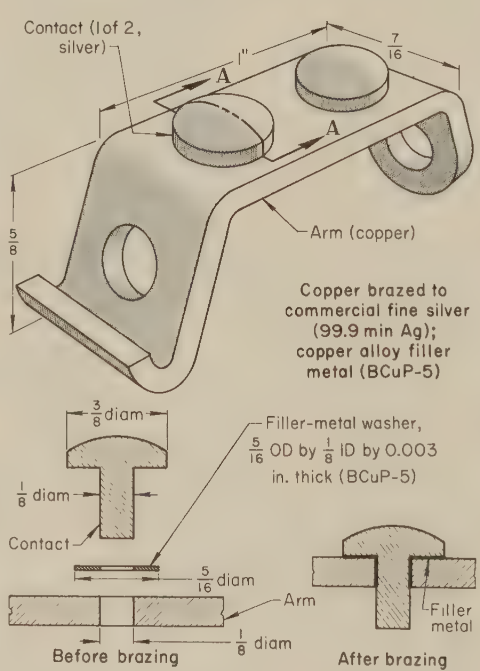


Fig. 2. Contact-arm assembly that was furnace brazed without protective atmosphere at 75 F below the liquidus of the filler metal (Example 635)

Accelerated Heating. Depending on the production rate required, and other factors, the maximum furnace temperature employed in a given brazing operation may vary considerably; it is not uncommon to employ a furnace temperature that exceeds that attained by the work load during the heating cycle in order to accelerate the heating rate and thereby to increase the production rate. Temperature differentials between the furnace thermocouple and the work being processed are usually established by experimentation and are controlled by regulating the elapsed time spent by the work load in the heating zone. At the higher furnace temperatures, and especially at temperatures above 1750 F, the substitution of a reducing protective atmosphere for a brazing flux will help to extend the life of heating elements and other furnace components by eliminating both oxidation and the corrosive reactions of volatilized flux. In the following example, assemblies were brazed at an accelerated heating rate in a prepared nitrogen-base atmosphere in a furnace equipped with a gastight muffle.

Example 636. Use of a Prepared Nitrogen-Base Atmosphere and an Accelerated Heating Rate (Fig. 3)

Figure 3 shows a bellows assembly consisting of a capillary tube of special DHP copper similar to alloy 122 but with a phosphorus content of 0.040 to 0.065%, a diaphragm plate of alloy 220 (commercial bronze, 90%), two diaphragms of alloy 172 (beryllium copper, 1.9%), and an extension point of alloy 340 (medium-leaded brass, 64.5%).

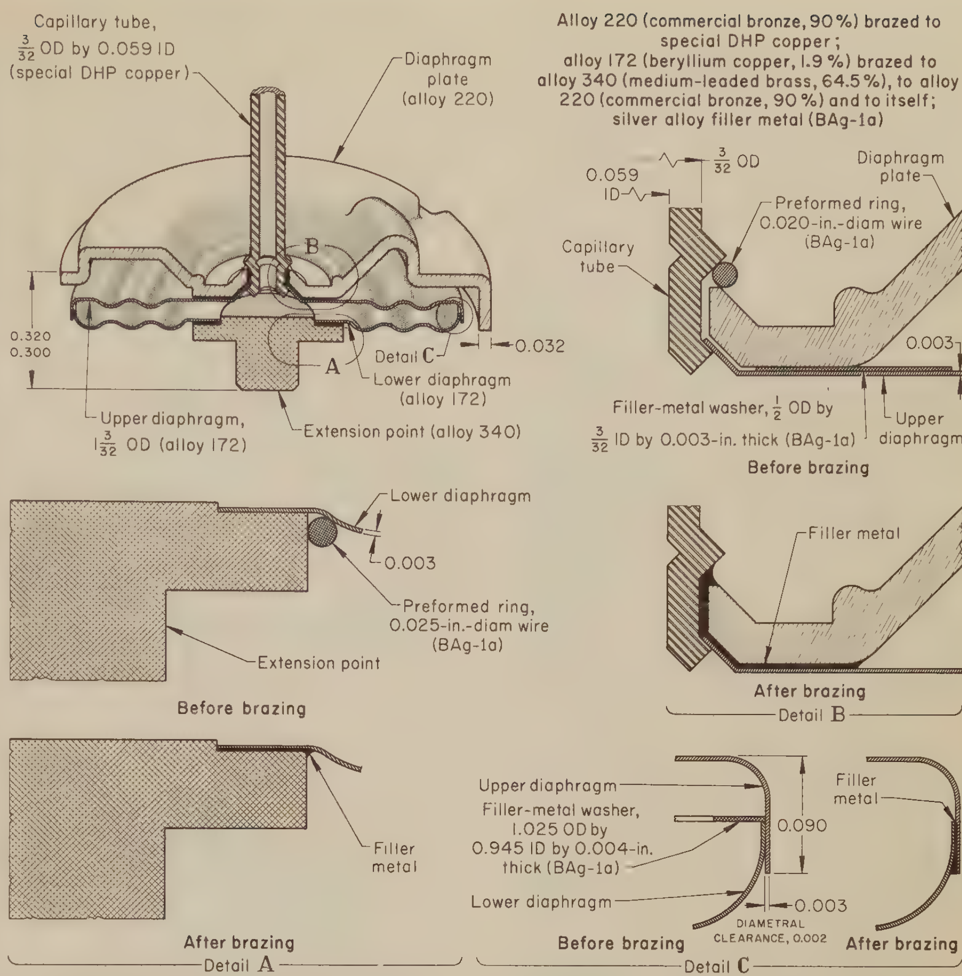
The upper diaphragm, the diaphragm plate, and the capillary tube were assembled as shown in detail B in Fig. 3, using two preforms — a ring of 0.020-in.-diam BAg-1a wire that fit over the tube, and a ½-in.-OD washer of 0.003-in.-thick BAg-1a filler metal with a 3⁄32-in.-diam center hole to accommodate the capillary tube. The tube was staked in two places to hold the subassembly together.

The lower diaphragm was assembled with the extension point, using a preformed ring of 0.025-in.-diam BAg-1a wire that fit snugly over the extension point (see detail A in Fig. 3). The diameter of the lower diaphragm was such that the lower diaphragm would fit snugly into the upper diaphragm. A preformed washer of 0.004-in.-thick BAg-1a filler metal was fitted into the cavity between the two diaphragms (see detail C in Fig. 3).

Originally, the assembly had been brazed in a brick-lined muffle furnace using an exothermic-base protective atmosphere. With this atmosphere, use of a flux was required. Although this was an inexpensive brazing method, the cost of removing the flux had to be added to the cost of the brazed product, and belt life was ⅛ to 1⁄12 that of belts operated in a furnace without using a flux.

To eliminate the difficulty and cost of removing flux and to obtain acceptable belt life at a high production rate, the brazing procedures were changed. The assemblies (without flux) were placed on the 12-in.-wide mesh belt of an electrically heated conveyor furnace. They traveled through the furnace at 30 in. per minute. Although the furnace was heated to 1800 F, to accelerate the rate of heating of the work, the assembly joints did not reach a temperature higher than 1175 F. The final adjustment of conveyor speed was determined by visual observation of filler-metal flow, rather than by recorded temperature of a thermocouple bead.

The furnace was equipped with a gastight Inconel alloy muffle. The protective atmosphere that eliminated the use of flux was a prepared nitrogen-base atmosphere containing 75% nitrogen and 25% hydrogen and having a dew point of −80 F or lower, obtained by processing the gas in a molecular-sieve drying tower. The atmosphere entered the furnace near the center and exited at both ends, where it was burned. The assemblies were cooled to 300 F before leaving the cooling chamber of the furnace. Production was 1200 assemblies per hour.



Conditions for Furnace Brazing

Furnace type	Electric mesh-belt conveyor(a)	Flux	None
Atmosphere	Nitrogen-base (75% N_2, 25% H_2)	Brazing temperature	1175 F(b)
Filler metal	BAg-1a preforms (see drawing)	Production rate	1200 assemblies per hour

(a) Furnace was equipped with a gastight Inconel muffle. Conveyor belt was 12 in. wide and moved at 30 in. per minute. (b) Furnace temperature was 1800 F, but the conveyor speed was high enough to ensure that assemblies did not reach a temperature of more than 1175 F.

Fig. 3. Bellows assembly, of copper and three different copper alloys, that was furnace brazed in a prepared nitrogen-base atmosphere at an accelerated heating rate (Example 636)

Furnace Atmospheres. Protective atmospheres are commonly used in the furnace brazing of copper and copper alloys, although there are numerous exceptions (see Example 635). Exothermic-base, endothermic-base, dissociated ammonia and other suitable prepared atmospheres are widely used to protect copper and copper alloys that are not adversely affected by hydrogen-containing gas mixtures at elevated temperature. Atmospheres and maximum dew points generally recommended for brazing copper and copper alloys are given in Table 4. Additional information on these atmospheres is given in the section on Protective Furnace Atmospheres in the article on Furnace Brazing of Steel (page 597). Detailed information regarding the generation of exothermic-base, endothermic-base, and dissociated ammonia atmospheres is given in the article "Furnace Atmospheres", on pages 67 to 84 in Volume 2 of this Handbook.

As shown in Examples 634 and 636, it is sometimes possible, depending on base-metal and filler-metal combinations, to avoid the use of a brazing flux by brazing in either a dry hydrogen or a prepared nitrogen-base atmosphere. These are among the more expensive furnace atmospheres; however, at low dew points, they have the advantage of being highly reducing. Prepared exothermic-base atmospheres are considerably less expensive and are effective in preventing oxidation at elevated temperature, but the reducing potential of these atmospheres is limited because hydrogen content does not exceed about 13%, and consequently they cannot be used as a substitute for a chemical flux. In the following example, nickel silver tableware handles were furnace brazed in a prepared exothermic-base atmosphere, using a silver alloy filler metal and chemical flux.

Table 4. Recommended Protective Atmospheres for Furnace Brazing of Copper and Copper Alloys

Base metal(a)	Suitable atmospheres	Maximum dew point, F
Coppers and phosphor bronzes	Lean or rich exothermic	20
	Reacted endothermic	20
	Dissociated ammonia	20
Red brasses (low zinc)	Purified, lean exothermic	10
	Reacted endothermic	10
	Dissociated ammonia	20
Yellow brasses (high zinc), leaded brasses, tin brasses (high zinc)	Purified, lean exothermic	−40
	Reacted endothermic	−20
	Dissociated ammonia	20
Silicon and aluminum bronzes	Purified, lean exothermic	−40
	Dissociated ammonia	−40
Copper nickels	Lean or rich exothermic	20
	Reacted endothermic	20
	Dissociated ammonia	20
Nickel silvers	Purified, lean exothermic	−40
	Reacted endothermic	−20
	Dissociated ammonia	20

(a) See pages 338 and 476 for alloy classifications and properties.

Example 637. Brazing Nickel Silver in an Exothermic-Base Atmosphere, Using a Conventional Flux (Fig. 4)

A filler metal containing 75% silver, 22% copper and 3% zinc was used to braze the nickel silver tableware handles like the one shown in Fig. 4. The handles were brazed in an electrically heated mesh-belt conveyor furnace using an exothermic-base atmosphere, using a type 3A flux.

The handles were made of alloy 757 in two different stock thicknesses, 0.025 and 0.040 in. The halves of the hollow handle were formed by dies in a drop hammer in two stages — breakdown and final shaping. The cut and fractured edges of the halves were smoothed on a belt grinder, after which a light coating of type 3A flux was applied to the edges with a rubber roller.

The halves were assembled and held together by lightweight stainless steel fixtures that contacted the halves near their midpoints rather than at the joint line, thereby maintaining joint clearance at 0.002 in. or less. One piece of filler-metal wire weighing 0.009 troy oz was dropped into each assembly, and the assemblies were placed on two nonmetallic bars in a rack. The racks were then placed on the conveyor belt of the brazing furnace. The assemblies were in the high-temperature (1650 F) zone of the furnace for approximately 9 min, after which they passed through the cooling zone. They were washed in hot water to remove the flux as soon as they were discharged from the cooling zone.

The high-silver alloy was expensive, but because very little was used for an assembly, filler-metal cost was insignificant. This alloy was selected for its excellent flow characteristics and was required to braze a joint more than 9 in. long with an absolute minimum amount of wire. Brazing at 1650 F, instead of at a lower temperature, reduced the number of rejects and increased the amount of alloying.

Assembly for Brazing. The component parts to be furnace brazed must be assembled in an essentially fixed position, with filler metal preplaced, before entering the furnace, and they must be capable of maintaining this position throughout brazing and cooling. Self-jigging is the preferred method of assembly. An assembly is self-jigging when its component parts incorporate design features that will ensure that each component, when assembled, will remain in proper relationship throughout the brazing cycle without the aid of auxiliary fixtures. Self-jigging can be accomplished by numerous methods (see page 603 in this volume).

When self-jigging is not feasible or when the assembly requires positioning or support in addition to that provided by self-jigging, auxiliary fixtures are used. These fixtures may take the form of a simple bracket or wire stand, ceramic blocks, clamps, or cast supports.

Venting Fully Enclosed Assemblies. Fully enclosed assemblies, whether assembled by self-jigging or supported by auxiliary fixturing, must be vented to permit the escape of entrapped air. When heated, entrapped air expands and, unless adequately vented, escapes from a sealed assembly in the area of the joint, resulting in flux spatter, joint porosity, and misalignment of brazed components. A small pinhole or slot, located near the top of the assembly but safely away from the area of the joint, is usually sufficient to provide adequate venting and to avoid damage to the joint. A more ingenious, though simple, method of venting is described in the following example.

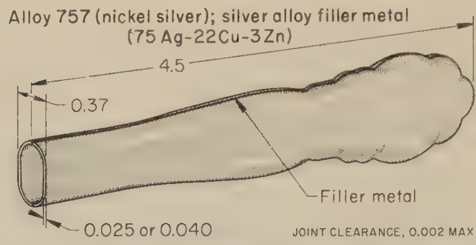


Fig. 4. Hollow tableware handle made by furnace brazing two formed halves under protection of exothermic-base atmosphere (Example 637)

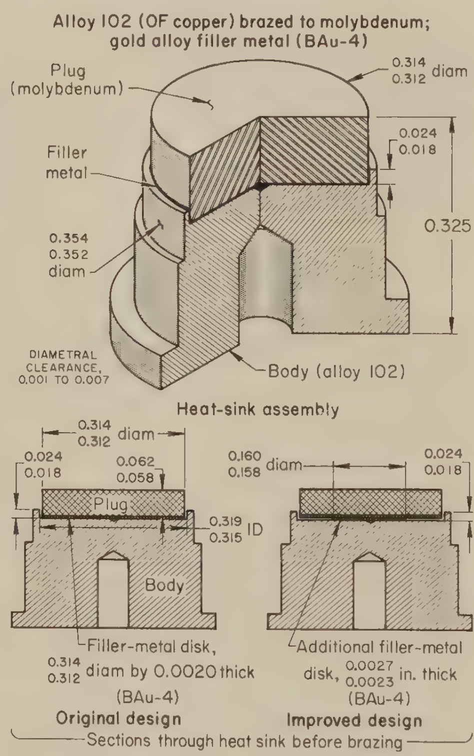
Example 638. Improved Venting by Use of an Additional Filler-Metal Preform (Fig. 5)

The heat-sink assembly shown in Fig. 5, which was used in an electrical circuit, was made by furnace brazing a molybdenum plug into a 0.315/0.319-in.-diam recess at the top of an alloy 102 (oxygen-free copper) body. The brazed assembly was subsequently plated.

Originally, the assembly was brazed using a single preformed disk of BAu-4 gold alloy filler metal of the same diameter as the plug (0.312/0.314 in.) and of almost the same diameter as the recessed hole, and 0.0020 in. thick (about one-tenth the depth of the recessed hole). With this design, there was no escape route for entrapped air, which expanded when heated and, at brazing temperature (1800 F), bubbled through the molten filler metal, leaving either small visible vent holes or invisible voids — depending on the viscosity of the molten metal when the bubble was formed. (Voids and vent holes trap liquids that eventually cause corrosion and, in electrical equipment, adversely affect the functioning of components.)

The visible vent holes were cause for immediate rejection; the voids, which were hidden under a thin skin, resulted in added expense, because often they were not discovered until the plating operation, when the preliminary acid cleaning opened the defect.

To improve venting, an additional disk of BAu-4 filler metal, 0.158/0.160 in. in diameter, was placed under the larger-diameter first disk to raise it and the molybdenum plug and allow passage of entrapped air (see "Improved design" view in Fig. 5). Results of the venting improvements, in terms of the percentage of rejections after brazing and at plating inspection, are given in the table with Fig. 5. Additional brazing conditions are also given in the table appearing with Fig. 5.



Conditions for Furnace Brazing

Furnace type	Electric mesh-belt conveyor(a)
Atmosphere	Dry hydrogen
Filler metal	BAu-4 disks (see drawing)
Flux	None
Brazing temperature	1800 F

Inspection	Original design(b)	Improved design(c)
Rejection Rate for Voids and Vent Holes		
After brazing	2%	1.6%
At plating	21.4%	3.7%

(a) Three zone; entrance and cooling zones were water-cooled. Muffle cross section was 6 by 8 in. (b) 100 assemblies inspected. (c) 350 assemblies inspected.

Fig. 5. Furnace brazed heat-sink assembly for which the use of an additional, smaller-diameter disk of filler metal provided adequate venting (Example 638)

Torch Brazing

Torch brazing of copper and copper alloys follows the same basic principles and uses the same equipment as the torch brazing of steel (see the article on Torch Brazing of Steel, which begins on page 619). The properties of copper and copper alloys introduce certain specific considerations in torch brazing.

Applications. Joining components of various types of heat exchangers probably represents the largest field of application for torch brazing of copper and copper alloys; products include condensers, evaporators, air conditioners, radiators and refrigerators, all of which depend on the high thermal conductivity of copper. Torch brazed products that depend on the high electrical conductivity of copper include motor windings, reactor coils, switches, contactors and terminal leads.

Process Selection. The selection of torch brazing in preference to another brazing process, such as furnace or induction brazing, depends largely on feasibility and cost. In seven of the ten examples of torch brazing presented in this article, brazing by any other process was not feasible because of workpiece limitations.

Manual Torch Brazing. Low equipment cost is a major advantage in manual torch brazing, which is particularly useful for assemblies involving unequal masses. A brazer with moderate skill can adjust and apply the heating flame so that unequal masses will be brought uniformly to brazing temperature. Similarly, the brazer can apply the heat selectively to the joints of assemblies involving both large and small areas. The size of brazing flames may range from those of extremely small torches the size of a hypodermic needle, employed for electronic leads (see Example 648), up to those of large torches used in brazing assemblies weighing hundreds of pounds.

In the example that follows, manual torch brazing was used because of the number of joints, the need for differential heating because of variations in mass, and the small production run.

Example 639. Manual Torch Brazing of 32 Joints in a Heat-Exchanger Assembly (Fig. 6)

The heat exchanger shown in Fig. 6 required 32 brazed joints. Thirty tubes made of admiralty brass (uninhibited) were torch brazed to a red brass tube sheet, which then was torch brazed to a cast housing end of leaded red brass. The casting in turn was torch brazed to a yellow brass housing tube.

The various joints were brazed with a filler metal containing 92% copper and 8% phosphorus — similar to BCuP-2 and used for brazing in the range of 1350 to 1400 F.

In some of the products, the fluid to be used in the heat exchanger (such as transmission oil) was not compatible with the copper-phosphorus filler metal, and a filler metal containing at least 35% silver, such as BAg-2, was used.

Because of product complexity and the variety of joints and joint locations, manual torch brazing was the most practical method of joining the assembly.

Base-Metal Alloys. Although nearly all coppers and copper alloys can be brazed, the ones most often torch brazed are the oxygen-free coppers and the copper-zinc alloys (see page 338). The base metals dealt with in examples of torch brazing in this article are:

Alloy No.	Alloy name	Example No.
102	Oxygen-free copper	640
122	Deoxidized copper (DHP)	642, 643
172	Beryllium copper, 1.9%	645
230	Red brass, 85%	639
260	Cartridge brass, 70%	645
268	Yellow brass, 65%	639, 641
360	Free-cutting brass	645
442	Admiralty, uninhibited	639
715	Copper nickel, 30%	647
(SAE 40)	Leaded red brass (cast)	639

Several precautions should be taken when torch brazing certain coppers and copper alloys. Where it is necessary to braze oxide-containing (tough pitch) coppers, a reducing atmosphere in the flame should be avoided because it will promote hydrogen embrittlement. For these coppers, a neutral or slightly oxidizing flame and a short brazing cycle are advisable. The brasses are subject to volatilization of zinc when overheated or when held too long at brazing temperature.

Alloys containing elements that readily form refractory oxides (aluminum, beryllium, chromium and silicon) should be protected by flux and should not be exposed to an oxidizing flame.

One of the notable differences between the torch brazing of steel and the torch brazing of copper alloys is that steel can withstand very rapid heating rates whereas some of the copper alloys (the phosphor bronzes, for instance) are subject to cracking if heated too rapidly when the metal is under high restraint during brazing.

Filler metals commonly used for torch brazing of copper and copper alloys include the lower-melting BAg silver alloys, the lower-melting BCuP copper-phosphorus alloys, and the copper-zinc filler metal RBCuZn-A.

The BAg-1 and BAg-1a alloys have the lowest melting temperatures of all the filler metals used in torch brazing of copper and copper alloys, and possess excellent flow characteristics. These filler metals contain more silver than BAg-2 (see Table 1), and are therefore more costly. For this reason,

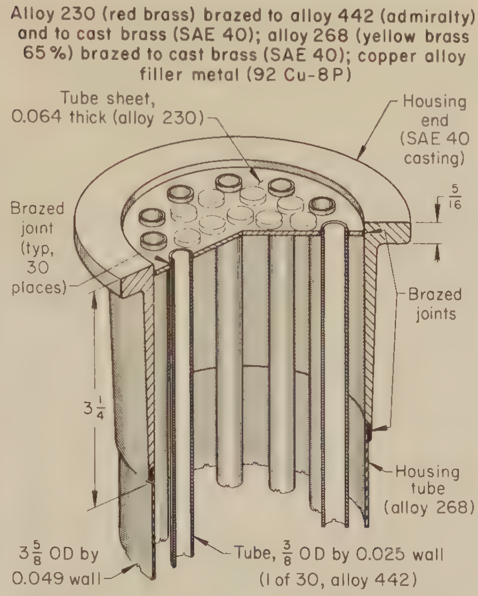


Fig. 6. Heat exchanger for which manual torch brazing was selected because of the number of joints (32), the need for differential heating, and the low production quantity (Example 639)

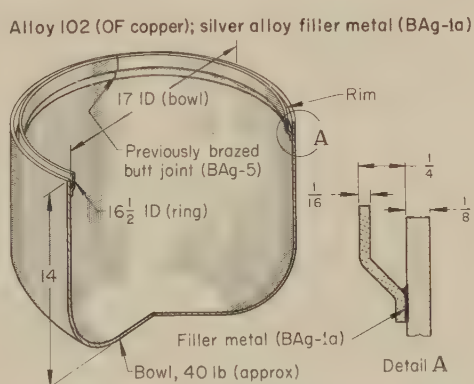
BAg-2 is sometimes preferred, even though it has a higher liquidus temperature than BAg-1 or BAg-1a.

Differences in the brazing-temperature ranges of various filler metals are used for step brazing; see page 648 in the article on Resistance Brazing and Example 599, as well as the example of silver brazing that follows.

Example 640. Use of Torch Silver Brazing for Low Production of a Bulky Assembly (Fig. 7)

The copper rim that was brazed to the inner edge of a copper bowl as shown in Fig. 7 formed a groove into which an end cap was later soldered. The brazed joint of this assembly had to be leaktight to a gas pressure of 15 psi.

The assembly was torch brazed without the use of a holding fixture. Heating was done with an oxy-natural gas torch. The



Conditions for Torch Brazing Rim to Bowl

Cleaning	Degrease and bright dip
Fixture	None(a)
Torch tip	3/16-in.-diam orifice
Fuel	Natural gas, 10 psi; oxygen, 70 psi
Filler metal	3/32-in.-diam BAg-1a(b)
Flux	Type 3A

(a) A gage was used to locate rim depth. (b) 2 oz per assembly.

Fig. 7. Bowl-and-rim assembly joined by torch brazing without the use of a fixture (Example 640)

sequence of operations was as follows: The rim was made by forming a 1/16-in.-thick by 1-in.-wide copper strip into a ring with a major outside diameter of 17 in. and butt brazing the ends with BAg-5 filler metal. The rim and bowl were degreased and bright dipped before being brazed together. The joint surfaces were brushed with a type 3A brazing flux. The rim was fitted to the bowl, using a gage to maintain proper depth, locally heated and tack brazed, using BAg-1a filler metal. Then the bowl was torch heated and the joint was brought to brazing temperature, the braze being completed by hand feeding BAg-1a filler metal. BAg-1a filler metal was used because of its low melting point, ability to make leaktight joints, and ability to withstand a subsequent forming operation. Also, the BAg-1a alloy was easily wetted by the tin-lead solder used when the end cap was joined to the bowl. BAg-5 filler metal was used to butt braze the ends of the rim because this alloy has a solidus temperature higher than the liquidus temperature of BAg-1a. Therefore, the butt-brazed joint was not affected during subsequent brazing of the rim to the bowl. Additional conditions for torch brazing the rim to the bowl are given in the table with Fig. 7.

The color of silver alloys does not match that of most copper alloys. Joints that are visible are plated or painted if appearance is important. Face-fed filler metal in the form of wire, powder, or a paste with flux is less neat in appearance than filler metal deposited from preplaced preforms. The latter, made from either wire or strip, are used in deep joints or in joints having a change in direction of the mating surfaces. The following example describes a production part that made use of preplaced filler-metal preforms, and that later was plated.

Example 641. Torch Brazing a Three-Piece Faucet Assembly With Silver Alloy Filler Metals (Fig. 8)

The brazed faucet assembly shown in Fig. 8 replaced a casting. This assembly was brazed from three alloy 268 (yellow brass, 65%) components, using radiant heat from two open gas burners, with integral reflectors, that burned natural gas and air. The mixing manifold and the spout were made in an automatic bar machine; the tube that connected them was made by drawing. The brazing operation was manual, although the burners were fixed.

Two identical fixtures were used for brazing, so that one assembly could be loaded while the other was being brazed. The spout end of the assembly took two preforms of BAg-1 filler metal: one, a piece of 0.003-in.-thick strip 1 in. long by 3/8 in. wide; the other, a 120° ring segment made of 0.047-in.-diam wire and formed to a 1/2-in. internal radius (see view at lower left and section B-B in Fig. 8). The mixing-manifold end of the assembly took a single preform made of 0.050-in.-diam BAg-1 wire in the form of a 60° segment of a ring with an inside radius of 7/8 in. (see view at lower left and section A-A in Fig. 8). Both joints were fluxed with type 3A flux. The fixtures were placed for brazing so that the radiant gas burners were at each end of the assembly, thus brazing both joints at the same time. Brazing temperature was approximately 1200 F. After brazing, the assemblies were cooled to about 600 F in air and then immersed in water to remove flux residue. Production rate was 70 assemblies per hour.

The brazed assemblies were leak tested by submerging them in water and applying air pressure at 90 psi. They were then decorative chromium plated. The brazed joints were invisible under the plating.

The BCuP filler metals contain phosphorus, which makes them self-fluxing

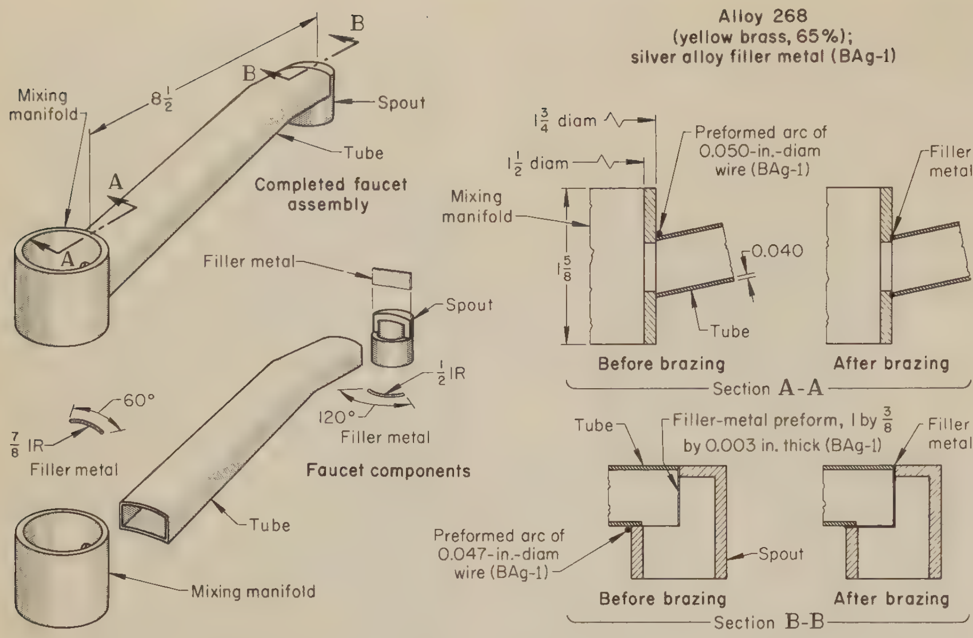


Fig. 8. Torch brazed faucet assembly that replaced a complex casting (Example 641)

on copper, but when these filler metals are used with copper alloys, a type 3A flux is usually advisable or necessary. These are the only filler metals used in torch brazing of copper and copper alloys that cannot be used on steel (because of the formation of brittle iron phosphides). When heated for too long a period, these alloys will liquate to an extent that will cause a decrease in joint strength. Rapid heating is therefore advisable.

Of the types used in torch brazing, BCuP-2 and 4 are the most fluid, and will fill joints having diametral clearances of 0.001 to 0.003 in. BCuP-5 will tolerate looser fits; typical diametral clearance is 0.001 to 0.005 in. The BCuP alloys are lower in cost than the silver alloy filler metals, and also provide a better color match on copper when the oxide film that forms on the filler metal during cooling has been removed. The next two examples describe the use of BCuP-5 in torch brazing.

Examples 642 and 643. Use of Self-Fluxing Filler Metal (BCuP-5) in Torch Brazing Copper Assemblies

Example 642 — Return Bends for a Heat Exchanger (Fig. 9). Return bends were brazed to heat-exchanger tubes as shown in Fig. 9. The tubes and return bends were of alloy 122 (phosphorus-deoxidized copper, DHP), ⅜-in. OD, with 0.016-in. and 0.020-in. wall thicknesses, respectively. Ends of the tubes were expanded to fit over the ends of the return bends with diametral clearance of 0.004 to 0.009 in. Brazed joints had to be leaktight at 400-psi pressure.

All parts were vapor degreased before brazing. Each leg of the return bends was mechanically fitted with a preformed ring of 0.030-in.-diam BCuP-5 filler wire, which does not require a flux when used for brazing copper. It was necessary that the wire ring fit tightly on the tube, so that the filler metal would be heated by conduction as the base metal was heated to brazing temperature. If heated directly, the filler metal might have melted before the base metal reached brazing temperature.

The joints were assembled and manually brazed using a Y-shape oxyacetylene torch with two tips (Fig. 9). The opposing tips surrounded the joint with flame, making heating faster and more uniform than it would have been with only one flame. The joint was brought up to temperature as rapidly as possible to prevent liquation of the filler metal. Each joint took 5 sec to braze. Since no flux was used, the brazed joints did not have to be cleaned.

The manufacturer also used multiple-flame gas-air burners for this type of product. Such equipment was used for high production on a given size of return bend. Multiple burners heated both joints at one time while the assemblies were on a conveyor line. Natural gas was used in preference to acetylene for economy and heating control; some joints were overheated and others underheated when using the rapid heating of acetylene. Radiant-type gas burners were also suitable for this type of work. Furnace brazing could not be used, because it was not permissible to heat the remainder of the assembly, including the aluminum fins. For this application, localized heat was essential.

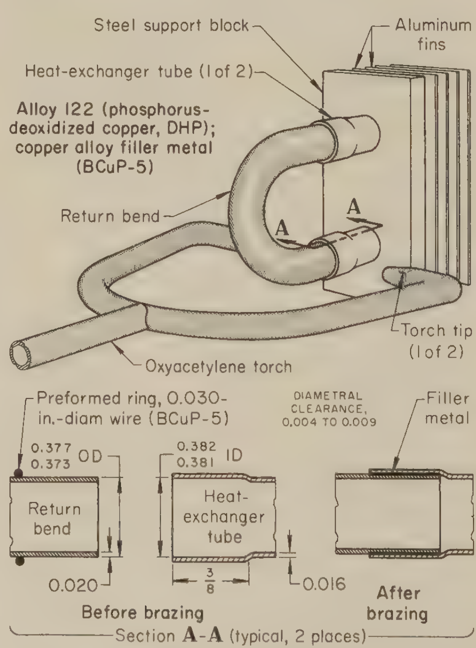

Fig. 9. Return-bend assembly of a heat exchanger, and a dual-tip torch used for rapid heating of the self-fluxing filler metal (Example 642)

Example 643 — Fin-Tube Assembly (Fig. 10). Circular cooling coils were made of two nested counterflowing segments coupled by a return bend (Fig. 10). Each coil segment consisted of 5½ turns of alloy 122 (phosphorus-deoxidized copper, DHP) tubing, 0.629 ± 0.005-in. ID by 0.042-in. wall, fitted with closely spaced fins about 1⁹⁄₁₆-in. OD. Four brazed joints were required, two at the return bend and one each at the inlet and outlet elbows. The return bend and elbows, also of alloy 122, were formed from ⅝-in.-OD by 0.042-in.-wall tubing. The diametral clearance for brazing varied from 0.002 to 0.005 in.; because of tubing tolerances, the return bends and the elbows were dressed as required, to obtain clearance within this range. The assembly had to be leaktight under 250-psi air pressure.

Manual torch brazing was selected as the most practical method of brazing the assemblies because (*a*) annual production was not high, (*b*) the workpiece was large compared with the joints to be brazed, (*c*) some manipulation of the assembly was needed, and (*d*) localized torch heating offered flexibility and freedom from general distortion.

The components were vapor degreased after forming. The two coil segments were then positioned in a rack consisting of four steel uprights (1-in. by ¼-in. steel flats) mounted on a circular base. A 0.109-in.-diam rod of the self-fluxing brazing alloy BCuP-5 was selected for filler metal to eliminate the need for flux application and removal. An available protective atmosphere (a furnace gas containing 1 to 2% CO, 10 to 12% CO_2, remainder nitrogen) was piped through the tubing during brazing to protect the internal surfaces from oxidation.

The joints were heated to brazing temperature with a manual oxy-natural gas torch, the natural gas being supplied at approximately 1 psi. The filler metal was face fed. The return-bend joints were brazed first; then the inlet and outlet elbows were correctly positioned and brazed. After brazing, the coil was strapped with flat brass bars and bolts and removed from the holding rack. Production rate averaged about 1½ assemblies per hour.

The BCuP filler metals are supplied as wire, rod and powder. BCuP-1 and BCuP-5 alloys are also available as strip. Like several other filler metals available in strip or sheet form, BCuP-5 is also produced by some manufacturers as a clad sheet ("brazing sheet") having a copper core and a cladding of BCuP-5 alloy on both sides. Clad brazing sheet is cut into strips and placed in joints or on surfaces that cannot be filled with other forms of filler metal. An application that made use of a special strip clad with BCuP-5 is described in Example 648.

The copper-zinc filler metal used in torch brazing is RBCuZn-A, which has the highest brazing temperature range of the filler metals considered here. Overheating must be avoided, both to protect the base metal and to prevent voids in the braze due to vaporization of the zinc.

Corrosion resistance is a consideration in selection of filler metal. Filler metal of inferior resistance can be selectively attacked. For example, RBCuZn-A is inferior in corrosion resistance to copper, copper-silicon and copper-nickel alloys. The silver alloy brazing filler metals have good corrosion resistance. For the brazed heat exchangers discussed in Example 639, 92Cu-8P filler metal was not satisfactory when the heat-exchanger fluid was a transmission oil, and a silver alloy filler metal was required.

Fluxes. Selection of flux for torch brazing of copper and copper alloys depends not only on the filler metal used (as it does for brazing of steel), but also on the base metal. Some copper alloys form refractory oxides, and this influences choice of flux.

When a silver alloy filler metal is used in brazing copper, or in brazing a copper alloy that contains no elements that cause it to form refractory oxides (aluminum, beryllium, chromium and silicon), a type 3A flux is used. The same flux is used when brazing these alloys with a BCuP filler metal. When brazing the copper alloys that do form refractory oxides, a more active flux is usually required. For instance, the aluminum bronzes require a type 4 flux to inhibit the oxidation of aluminum.

"Gas fluxing", by entraining volatilized flux in the gas flame, is used in torch brazing copper and copper alloys. The equipment for and use of this fluxing method are described on page 629 in the article on Torch Brazing of Steel. When used on copper and its alloys, the purpose of gas fluxing is to protect the surface of the base metal from becoming oxidized or discolored. It thus eliminates postbraze cleaning. Joint surfaces are always first protected with an appropriate flux. This secondary use of a gas flux is illustrated in the following example.

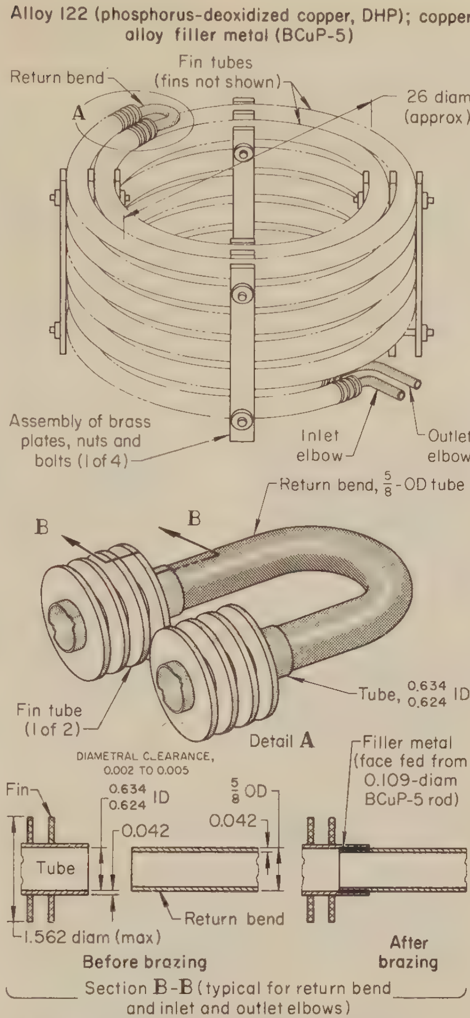

Fig. 10. Fin-tube assembly showing four joints that were manually torch brazed using self-fluxing filler metal (Example 643)

Example 644. Use of Gas Fluxing To Prevent Oxidation of Work Metal During Brazing (Fig. 11)

Two types of flux were used when torch brazing a capillary tube system consisting of a bulb and two capillary tubes (Fig. 11). One type was necessary for brazing. The other, a gas flux fed through the flame, was used to prevent oxidation and discoloration of the copper assembly. The torch used oxyacetylene and had a standard brazing tip and conventional gas-fluxing equipment. The gas flux was composed of 71½% methyl borate and 28½% acetone. BAg-1 filler metal was used, although other filler metals, such as BAg-1a and BCuP-2 to 5, would have been satisfactory.

After five assemblies had been loaded on a five-station manually operated fixture, the joint surface of each tube was brushed with a small amount of type 3A flux to ensure penetration of flux and filler metal into the joint. The joint was heated with the oxyacetylene flame containing the gas flux. The torch was passed up and down over the assembly to give it a flux coating, to prevent oxidation during brazing. The torch was then held close to the bulb to ensure even heating, because the bulb portion had the thicker wall. The filler metal was hand fed to complete the joint. The brazed assembly was removed and quenched with water to cool it and remove the flux. This sequence of operations was repeated for each of the five assemblies in the fixture. The finished assembly was bright and free of deposits.

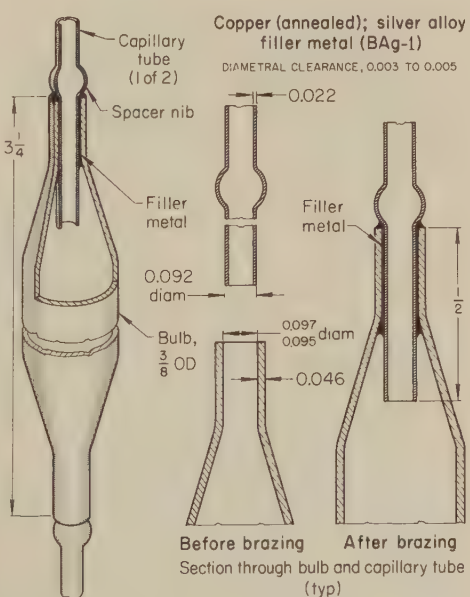

Fig. 11. Bulb and capillary tubes joined by torch brazing, using gas fluxing to prevent oxidation, in addition to a type 3A brazing flux (Example 644)

Fuel Gases. The fuel-gas mixtures generally used in torch brazing of copper and copper alloys are oxyacetylene, oxy-natural gas, oxy-propane, oxy-hydrogen and air–natural gas. The oxy-fuel gases are highest in cost, flame temperature and heating rate, with oxyacetylene the highest in the group in each respect. Oxy-fuel gases are widely used in manual torch brazing, where temperature can be controlled by torch manipulation. The cost advantage of air–natural gas is exploited particularly in mechanized and automatic high-production torch brazing, where the lower flame temperature affords protection from damage due to overheating. Desired heating rates are obtained economically by using high flow rates, together with multiple torches or radiant-type burners.

Neutral or slightly reducing flames are used to help the fluxes in preventing oxidation of base-metal surfaces.

Although high heat input is necessary to overcome their high thermal conductivity, many copper alloys cannot withstand the rapid heating rates that can be used on steel. Under too rapid heating, high thermal expansion can cause local stresses, resulting in distortion and cracking in some alloys. Accidental overheating will cause damage to copper and copper alloy assemblies more readily than to those made of steel. The use of gases of lower flame temperature requires less skill in avoiding these difficulties.

Although the use of oxyacetylene flames requires more care to avoid overheating than does the use of other types of flames, oxyacetylene flames heat faster. In the following example, oxyacetylene was well suited to the purpose of bringing the joints to temperature quickly in order to localize the heat to avoid loss of the effects of cold work, and to keep labor costs low.

Example 645. Torch Brazing of Five Copper Alloys and a Stainless Steel in a Bourdon-Tube Spring Assembly (Fig. 12)

The measuring element of a 5000-psi pressure gage was a bourdon tube made of alloy 172 (beryllium copper, 1.9%), coiled to form a spring that deflected under internal pressure. The spring assembly, shown in Fig. 12, required four brazed joints. Section A-A in Fig. 12 shows two joints that were brazed simultaneously: a type 304 stainless steel capillary tube brazed to a copper bushing, which was brazed to the inside of the beryllium copper bourdon tube. At section B-B, in Fig. 12, the bourdon tube was brazed to a take-off arm of alloy 360 (free-cutting brass), which in turn was brazed to a take-off lug of alloy 260 (cartridge brass, 70%), as shown in section C-C in Fig. 12.

Torch brazing was used because it was simpler to control the amount of heat input required for the different joints by torch than by induction brazing. Furnace brazing was considered unsatisfactory because the entire spring would have been exposed to the brazing temperature, which would have removed the effects of cold work and thus have reduced the potential mechanical properties obtainable by the heat treatment after brazing.

A fixture was used to position the components accurately for brazing. The parts were fluxed with type 3A flux, assembled in the fixture, and heated by an oxyacetylene torch. Silver alloy filler metal (BAg-1a) was hand fed to the joints. Immediately after the filler metal had solidified and while the assembly was still hot, it was plunged into cold water to remove the flux residue, and to limit the annealing action on the beryllium copper bourdon tube.

After brazing, the springs were age hardened and then bright dipped. Each assembly was made, quenched and dried, ready for heat treatment, in 2.25 min. At $3 per hour, this represented a direct labor cost per piece of $0.113.

Mechanized and automatic torch brazing equipment and operations are the same as those applied on steel assemblies, except for the special considerations discussed earlier in this section. Mechanized and automatic torch brazing of steel is discussed on pages 623 to 627 in this volume.

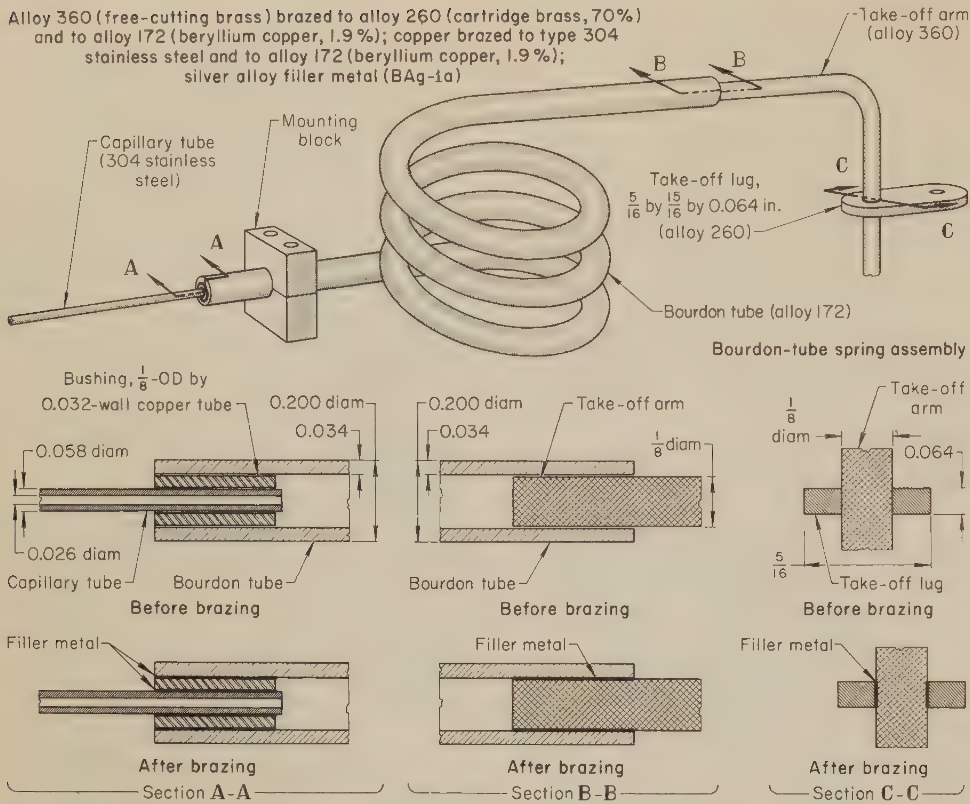

Fig. 12. Torch brazed bourdon-tube spring assembly with components of five different copper alloys and a stainless steel (Example 645)

Mechanized torch brazing is most widely used in the manufacture of air conditioners, radiators and other types of heat exchangers that utilize hairpin coils of copper tubing with aluminum fins. Conveyor belts and turntables are used extensively for both mechanized and automatic torch brazing. The following example illustrates the use of a turntable in an operation that was wholly automatic except for assembly.

Example 646. Use of an Eight-Station Turntable for Automatic Brazing of Bulb-and-Tube Assemblies (Fig. 13)

The eight-station automatic setup shown in Fig. 13 replaced a manual torch brazing setup that required two operators and utilized a rotating fixture for brazing copper bulb-and-tube assemblies. Production rate (about 700 joints per hour, gross) was not increased with the automatic method, and improvement in quality was negligible. However, only one unskilled operator was needed for the automatic method. Therefore, the cost of direct labor was reduced more than 50%.

The sequence of operations is given in Fig. 13. The air – natural gas torches at stations 4, 5 and 6 were adjusted to produce neutral or slightly reducing flames. Filler metal was BAg-1 in flux-paste form.

The completed assemblies were leak tested with air at 60 psi. Rejection rate was 1%, which was considered satisfactory. The joints were clean and ductile.

Joint Design. For the more widely used silver alloy and copper-zinc alloy filler metals, diametral clearances of 0.002 to 0.005 in. are suitable. For the BCuP filler metals, diametral clearances differ; clearances of 0.001 to 0.003 in. are suitable for BCuP-2 and BCuP-4, and 0.001 to 0.005 in. for BCuP-5.

Much torch brazing is done by face feeding of filler metal, and when this is desired, joints should be limited to a depth that can be quickly and adequately fed by the form of filler metal used. Deep joints and those that

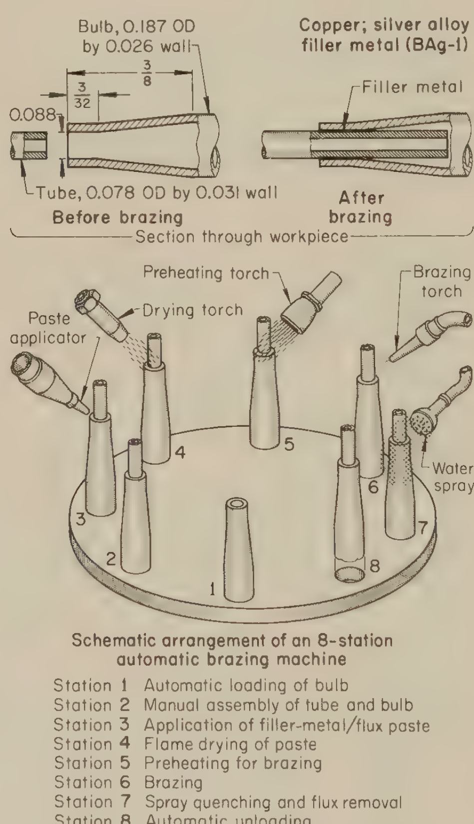

Fig. 13. Bulb-and-tube assembly brazed by mechanically held torches on an eight-station turntable (Example 646)

change direction sharply will require the use of preplaced filler metal.

The following example involves a type of failure that was corrected by changing from a corner joint that placed the braze in tension, due to bending, to a lap joint that placed the braze in shear and enlarged the area of contact of the joint.

Example 647. Change in Joint Design That Eliminated Failures Due to Leakage (Fig. 14)

The torch brazed assembly shown in Fig. 14 was the heat-dissipation section of a cooling unit for electronic equipment. Ethylene glycol solution circulated through the tubes and the water box. Freon vapor condensed on the outside surfaces of the tubes and tube fins (not shown in Fig. 14), dropping off as a liquid. All components shown were made of alloy 715 (copper nickel, 30%). The tube fins were made of copper, mechanically attached. The assembly was brazed with a manually operated oxy-natural gas torch, using BAg-2 filler metal.

The view at lower left and detail A in Fig. 14 show the joint between the water box and the cover as originally designed. A high percentage of these joints failed in service on the inside corner of the joint, due to tensile loading. Varying pressure loads imposed bending moments on the box walls, causing the joint to act like a hinge. The braze itself was far from perfect. Only about 1/16 in. of the joint depth was a true braze; the remainder had only the inherent strength of the silver alloy filler metal. Small defects nucleated leaks that caused loss of cooling and failure of the system.

To reduce stress concentrations, the cover plate was redesigned as a formed cup, which provided a lap joint that placed the braze in shear and increased the joint area considerably. The improved design of the cover assembly and the joint are shown in the lower middle view and detail B in Fig. 14. No field failures were reported for several thousand of the redesigned units.

Precision Torch Brazing. Although conventional torch brazing is capable of joining parts only a fraction of an inch in size, some small assemblies require the use of special equipment. When joining copper and copper alloy parts of this type, heat control is the principal difficulty, but other factors may be introduced. For instance, many electrical and electronic joints are not only small but are located close to components that can be functionally disabled by heat, spatter, and the removal of flux residues. If allowed to remain, an active flux will, in time, corrode the joint.

One method of meeting these problems is the use of a miniature oxy-hydrogen torch that utilizes a special gas generator. Torch tips are made from several sizes of hypodermic-needle tubing. Oxygen and hydrogen are generated by electrolysis of water, in the exact ratio required for complete combustion. (Alcohol vapor can be added to the fuel line to impart a blue cast to the otherwise less-visible flame.) This technique, when used with a self-fluxing BCuP-5-clad brazing sheet, proved advantageous in joining copper leads, as described in the next example.

Example 648. Technique for Brazing 0.008-In.-Diam Wires to 0.010-In.-Thick Terminals (Fig. 15)

Terminals to be attached to 0.008-in.-diam wire leads, as shown in Fig. 15, were made of a 0.004-in.-thick core of copper clad on both sides with 0.003-in.-thick layers of BCuP-5 brazing filler metal. At first,

several experimental assemblies were made by gas tungsten-arc welding. This method was unsatisfactory because the heat could not be controlled. Arc starts occurred in a burst that made observation by the operator difficult.

Actual production joints were made initially by capacitor-discharge resistance brazing. Expulsion from the joint caused spatter to be lodged on surfaces or concealed in crevices, where it changed the electrical properties of the device by induction or short circuiting. Inspection of the joint was difficult and time consuming, and repair time was excessive.

By changing to torch brazing, using a special oxy-hydrogen torch, the procedure was brought under control. Quality and reliability of the joint were greatly improved.

During the time when operators were learning to use this process, production rates were lower than before. After approximately three months, operator skill increased to the point where production time was equal to or slightly less than with the resistance brazing process. An over-all saving in time was realized because rework for broken or improperly brazed joints was almost eliminated. Operators came to prefer this method of brazing because they were better able to monitor their own work; they knew immediately if the joint was acceptable because they could watch the melting of filler metal and the formation of the fillet. All work was observed under low-power magnification.

The procedure was to form the prestripped wire lead manually so it would lie flat on the terminal to which it was to be brazed (Fig. 15, upper view). Torch heat was then applied until the fillets were formed. The wire was held in position by tweezers or an orange stick.

The oxy-hydrogen gas supply was derived from electrolysis of water at the rate of 6 cu ft per hour. This was equal to a heat output of 3500 Btu per hour. A methyl alcohol booster was used to add a bluish cast to the flame to permit easier control by the operator. The torch tips were made from 0.009-in.-ID hypodermic-needle tubes. A flashback arrester was incorporated with each torch.

A schematic diagram of the gas generator and equipment components required for one brazing station are shown in the lower view in Fig. 15. Cost for one generator and torch was $525. Production rate was 35 to 40 joints per hour for forming, assembly and brazing. As many as eight brazing stations could be operated from one generator.

Quality was verified by 100% operator inspection of the joints as they were made.

Induction Brazing

The efficiency of heating by induction for any purpose varies directly with the electrical resistivity of the alloy. Brass, because it has higher electrical resistivity, can be heated more efficiently than copper; steel, which has even higher resistivity, can be heated more efficiently than brass. In terms of the high-frequency power input and the time required to heat one pound of metal in a joint assembly to a brazing temperature of about 1300 F, a power input of 15 kw (at 450 kHz) will heat a steel joint to this temperature in about 16 seconds, whereas brass will require about 30 seconds, and copper about 55 seconds (Fig. 16).

Advantages. The general advantages of induction brazing (see page 631) are applicable to copper and its alloys.

In several examples in this section, the localized heating obtainable with induction brazing was advantageous. In the next example, induction brazing minimized warpage and postbraze cleaning, and required less operator skill than would have been needed for torch brazing.

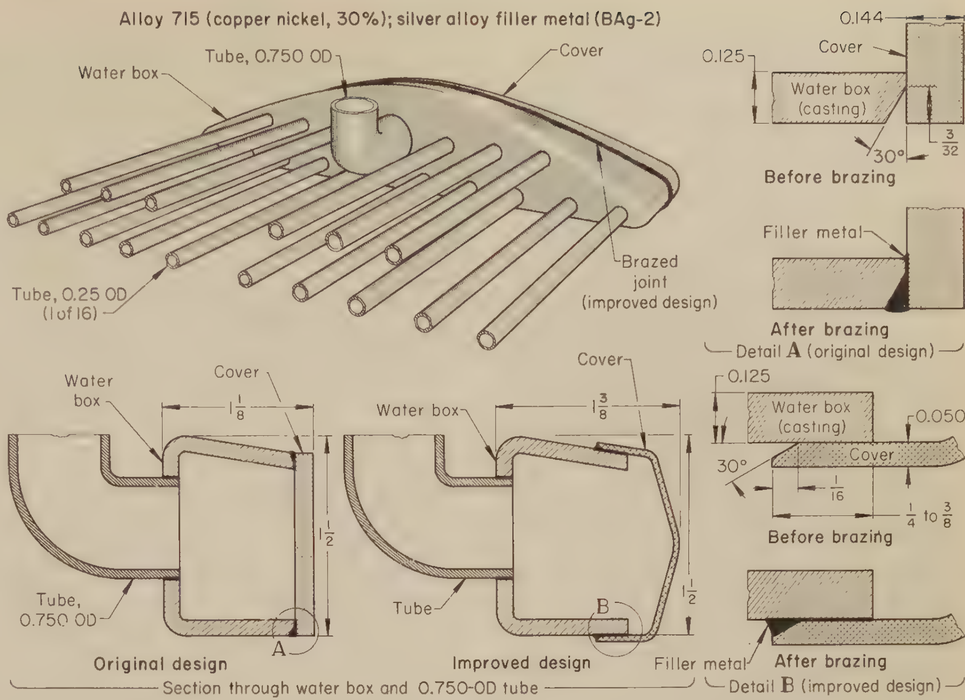

Fig. 14. Change in joint design that eliminated leakage in a torch brazed component of a cooler for an electronic system (Example 647)

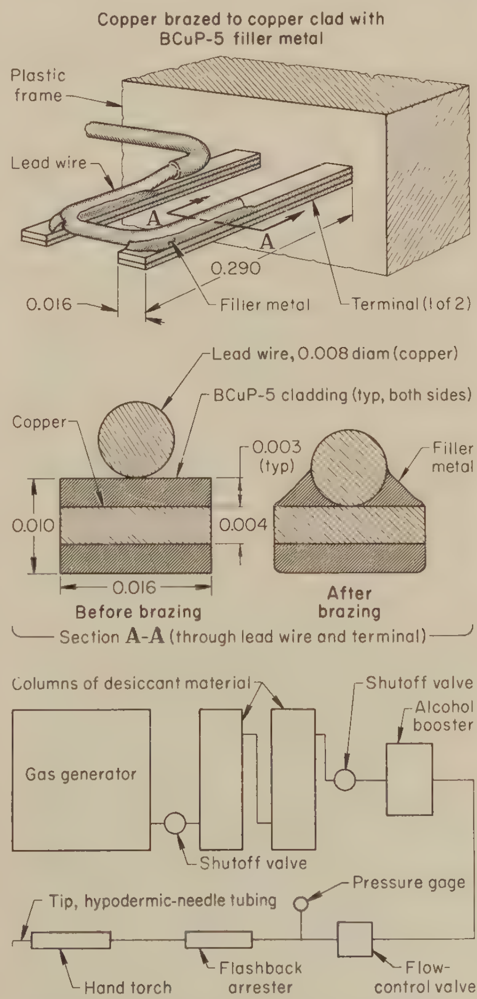

Fig. 15. Assembly of a lead wire and terminals that was brazed with a special oxy-hydrogen torch and self-fluxing filler metal, sectional views of the joint, and schematic of equipment layout (Example 648)

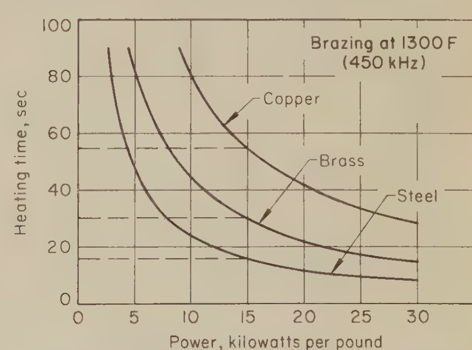
Example 649. Use of Induction Brazing To Minimize Warpage and Postbraze Cleaning (Fig. 17)

Alloy 110 (ETP copper) tubes ¾ in. in outside diameter were induction brazed to hot-water-tank covers, formed from alloy 230 (red brass, 85%), using the setup shown in Fig. 17. The resulting joints had to be leaktight at a pressure of 300 psi.

As shown in Fig. 17, the holding fixture, which was made of cemented-asbestos board, had a retaining shoulder at the edge and a stop at the center to support the pipe. The fixture was raised and lowered manually on a rack to move the joint into and out of the inductor.

Tubes and covers were degreased in trichlorethylene and bright dipped before being assembled for brazing. The joint surfaces were brushed with flux before the parts were assembled. A preformed ring of 0.050-in.-diam BCuP-5 filler-metal wire was placed over the tube, as shown in detail A in Fig. 17. The assembly was then raised to position in the single-turn inductor, where it was heated for 28 seconds, and then lowered and unloaded from the fixture.



Power is expressed as kilowatts required to heat one pound of metal at the joint to 1300 F. (SOURCE OF DATA: W. D. Wilkinson, *British Welding Journal*, Oct 1965)

Fig. 16. Power input and heating time required for high-frequency induction brazing of steel, brass and unalloyed copper

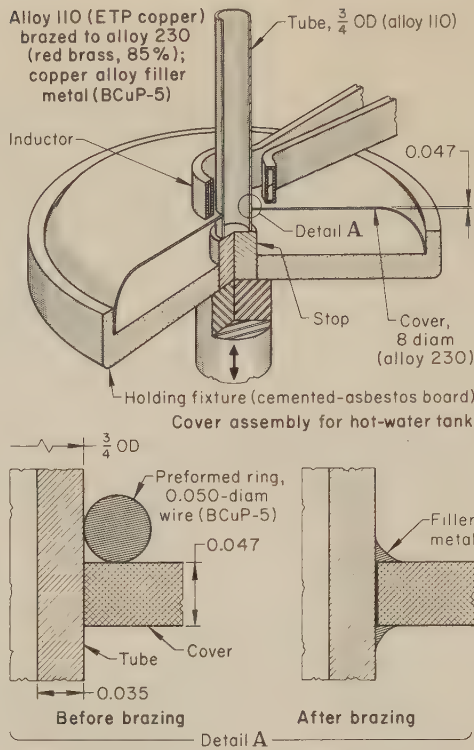
Selection of induction heating for this application was based primarily on the ability of the process to localize heat in the joint region, and thereby to minimize warpage and postbraze cleaning. The same assembly could have been brazed with a torch, but induction brazing provided for programed heat input and made possible the use of an operator with less skill than would have been required for torch brazing. Additional brazing conditions for the hot-water-tank assembly are given in the table accompanying Fig. 17.

Limitations. One of the general limitations of induction brazing is the cost of induction heating equipment, which far exceeds the cost of torch brazing equipment and usually exceeds the cost of equipment for resistance brazing or dip brazing in molten salt. Because efficiency in heating copper and copper alloys by induction is generally lower than that for heating steel (Fig. 16), the power requirements, and consequently the cost of the equipment for achieving a given production rate, are proportionately higher.

Other general limitations of induction brazing that relate to the size and shape of assemblies that can be brazed, the design of inductors, and requirements for matching impedances, apply to the brazing of copper and copper alloys as well as to the brazing of steel and are discussed in the article on Induction Brazing of Steel, beginning on page 631. Limitations that relate more specifically to the brazing of copper and copper alloys by induction include heating rate and the avoidance of overheating, both of which are less amenable to control in induction brazing than in furnace brazing or dip brazing in molten salt. Consequently, the induction brazing of copper alloys that are susceptible to hot cracking or to dezincification is more problematical. Other difficulties unique to induction brazing that may arise in connection with the use of a flux are discussed later in this section under "Use of Fluxes".

Power supplies used in the induction brazing of copper and copper alloys, including motor-generator sets, solid-state units, and vacuum-tube units, are discussed at length in the article on Induction Brazing of Steel. That article, which begins on page 631, also reviews the criteria for selection of frequency and the circuit requirements for matching impedances — factors that are closely related to the selection of a power supply.

Frequently, in the induction brazing of copper and copper alloys, it is necessary to maintain loose coupling between the inductor and the load (workpieces). Under conditions of loose coupling, there are two methods for improving heating efficiency. If a variable output transformer is used, an additional tuning capacitor may be connected directly across the inductor to increase inductor current. As an alternative, a high-impedance output circuit, designed specifically for brazing nonferrous metals, may be employed. This circuit does not include a variable output transformer; rather, it is designed so that the inductor is an actual part of the tank circuit inductance, with a relatively high voltage and current in the work circuit.



Conditions for Induction Brazing

Power supply	Vacuum-tube unit, 10 kw, 450 kHz
Inductor	Single-turn
Filler metal	BCuP-5 wire, 0.050-in. diam, preformed to ¾-in.-ID ring
Flux	Type 3A (AMS 3410D)
Brazing time	28 sec per joint
Production rate	60 joints per hour

Fig. 17. Tank-cover assembly that was brazed by induction to minimize warpage and postbraze cleaning (Example 649)

Design of Inductors. Guidance in the design of inductors is presented in the article on Induction Brazing of Steel, which begins on page 631 and contains numerous examples of single-turn and multiple-turn inductors used in brazing applications. Although the use of single-turn inductors is not uncommon in brazing copper and copper alloys (see Example 649), the efficiency in heating and, to some extent, the control of heating rate are greatly improved with the use of multiple-turn inductors. In the following example, the control of heat input and distribution was critical, and excellent results were obtained at a relatively low operating frequency (10 kHz) using a three-turn inductor.

Example 650. Use of a Multiple-Turn Inductor To Control Heat Input and Minimize Over-Aging of Chromium Copper (Fig. 18)

Chromium copper (0.6% Cr) has high electrical conductivity (78% IACS) and develops optimum mechanical properties in the precipitation-hardened condition. After solution heat treatment, it is aged at 750 to 930 F. Heating for brazing is critical because the copper will over-age or partly anneal at temperatures above 930 F, the over-aging effect increasing with increasing temperature and time at temperature.

Consequently, in brazing a tungsten–silver alloy contact to a precipitation-hardened chromium copper post (see Fig. 18), heat input to the post required careful control in order to minimize over-aging. It was required that the joint have high electrical conductivity and impact strength, and that the chromium copper post retain its hardness and strength to resist distortion when subjected to repeated impact. Brazing the tungsten–silver alloy contact required the use of a nickel-containing silver alloy filler metal for adequate wetting. BAg-3 was chosen in preference to BAg-4 or BAg-13 because BAg-3 has a lower brazing range (1270 to 1500 F); induction brazing was selected in order to control heat input and minimize the duration of the brazing cycle. Optimum control of heat input to the chromium copper post was obtained using the square three-turn inductor shown in Fig. 18.

Before brazing, the chromium copper base was bright dipped, and the tungsten–silver alloy contact was cleaned with an abrasive cloth. Type 3A flux paste was applied to both components with a brush. They were then assembled with a disk of filler metal placed between them, as shown in Fig. 18. Power supply was a 50-kw, 10-kHz motor-generator set. When the brazing alloy melted and flowed, the contact was rotated to release any entrapped gases and improve wetting. Production rate was ten joints per hour.

Inductors for Mass Production. Induction heating is well suited for the mass production of brazed assemblies, primarily because it is possible to design inductors that will heat an endless line of assemblies as they are carried into the induction field by conveyor belt or turntable. Hairpin and pancake inductors are most widely used for conveyorized applications, because they do not obstruct passage of the assemblies as they travel through the induction field; inductors for conveyorized setups are described on page 635 in the article on Induction Brazing of Steel.

Because steel assemblies heat more efficiently, they are generally more adaptable to brazing in a conveyorized setup than are assemblies made of copper and copper alloys. However, an alternative design for use with copper alloys, provided sufficient power is available, is the multiple-station inductor. With this type of inductor, two or more (often as many as six) assemblies can be brazed simultaneously or in a selective sequence that permits loading at one or more stations while other stations are heating.

Examples 651 and 652, which follow, describe respectively the application of a conveyorized setup and a multiple-station inductor to the brazing of copper and copper alloy assemblies at high production rates.

Example 651. Use of a Conveyorized Setup for Induction Brazing of Connector Assemblies (Fig. 19)

Small connector assemblies, consisting of two alloy 360 (free-cutting brass) studs and an alloy 172 (beryllium copper, 1.9%) spring clamp (see Fig. 19), were induction brazed on a 5-ft-long conveyor at a rate of 1900 assemblies per hour, using a modified pancake-type inductor and a 2½-kw, 300-kHz vacuum-tube power supply.

The brass studs, which had a tapered bore, were brazed to the platform of the spring clamp in the position shown in Fig. 19. The critical portions of the assembly that could not be overheated without causing serious damage were the thin (0.015-in.) wall at the top of the studs and the receptacle portion of the beryllium copper spring clamp, which was precipitation hardened prior to assembly for brazing. Heating, therefore, had to be largely restricted to the area of the joint without disrupting the preferred flow of filler metal or interfering with the seating of the studs on the clamp platform.

Proper heating was obtained with the modified pancake-type inductor shown in cross section at lower right in Fig. 19. The inductor, which was made of 3⁄16-in.-OD copper tubing, consisted of four active turns and a shorted central turn to which was soldered a plate with a pair of 6-in.-long copper intensifier shoes. The upper part of the gap between the shoes was tapered to direct energy toward the joint and away from the thin walls of the studs. At the inductor entrance, the gap between the shoes was 5⁄16 in.; from the midpoint of the inductor, the gap width flared to ½ in. at the inductor exit. The assemblies were held in place by inserting the receptacle end of the spring clamp into ceramic holders; the holders were located ½ in. apart, and traveled on the conveyor chain at a speed of 16 in. per minute.

Stud and clamp components were bright dipped prior to assembly. The studs were hopper-fed into clamping cavities in a rotary indexing table. A preform of BAg-1 strip 0.180 by 0.350 by 0.003 in. thick was pierced, cut off and placed automatically on each pair of studs. The beryllium copper spring clamp was placed on each assembly by hand. The ends of the studs were staked to the clamp to make the assembly self-jigging. The staked assemblies were dipped in a 20-to-1 solution of hot water and type 3A flux and air dried on a screen. Then the assemblies were placed, spring clamp down, into the ceramic holders, as shown at lower right in Fig. 19, and passed through the inductor. Time at temperature was approximately 22 seconds. After being brazed, the assemblies were washed in hot water.

Example 652. Use of Two Four-Station Inductors for High-Production Brazing of Motor Armatures (Fig. 20)

In the production of motor armatures, copper end rings were induction brazed to both ends of 14 copper rivets that held the armature laminations (see Fig. 20), at a rate of 433 assemblies per hour (two joints per assembly) in two four-station, single-turn inductors, using a 5-kw, 450 kHz vacuum-tube power supply. Induction brazing was selected for this application partly because the rapid rate of heating left the magnetic properties of the silicon steel armature laminations relatively unaffected.

Each of the eight inductor stations contained a graphite bushing into which an armature assembly could be placed. The inductors and bushings were attached to graphite blocks that supported the armatures during the brazing cycle.

Silver-containing filler metal BCuP-5 was selected for its suitable brazing range and because it is self-fluxing on copper. Because the filler metal would not wet the graphite holders, there was no difficulty in simultaneously brazing rings to both ends of the armatures. Conductivity was adequate.

Before brazing, the copper rings were degreased and bright dipped. Each inductor station was loaded by first placing a copper end ring at the bottom of the graphite bushing, followed by a preform of brazing alloy. The armature was then inserted in the hole in the graphite block (see Fig. 20, section A-A), and a second ring of filler metal was placed on top of the armature, followed by another end ring of copper. When one of the four-station inductors was loaded in this manner, power was applied and the brazing cycle began. The operator then began loading the second four-station inductor.

Use of Fluxes. The proximity of a moist or liquid flux to an uninsulated high-voltage, high-amperage inductor is often a source of difficulty unique to induction brazing. The difficulty increases with the tightness of coupling (the narrow distance across the air gap between inductor and workpiece) that is often required to heat copper and copper alloys efficiently.

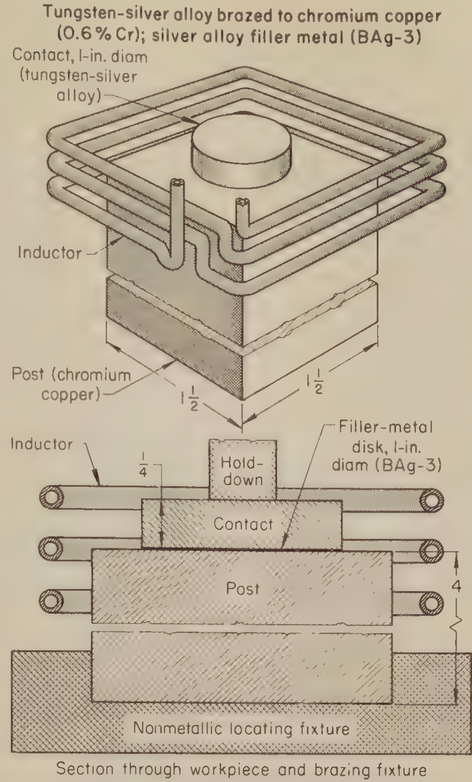


Fig. 18. Tungsten – silver alloy contact and chromium copper post in position for induction brazing, using a three-turn inductor (Example 650)

When the base metal heats, and the water in a moist flux is driven off in the form of steam, there is often a violent sputtering, followed by high-voltage arcing due to shorting between inductor and workpiece. If the arcing is of sufficiently high intensity, it will puncture the thin wall of the inductor tubing at one or more points, releasing a high-pressure spray of cooling water from the inductor. Damage to expensive inductors, fixtures and assemblies due to flux-induced arcing can be considerable. Although relatively uncommon, it is possible for a molten flux, by virtue of its electrical conductivity, to sputter when driven by field forces in a field of high intensity.

The hazard of arcing can be substantially reduced by protecting the inductor with an insulated cover, such as woven fiber-glass sleeving, by grounding the inductor, by allowing the water in moist fluxes to dry before they are heated, or by using a low-sputtering type of flux.

Avoiding the Use of Flux. In the earlier discussion of filler metals and in Example 652, it was noted that some filler metals, notably those in the BCuP series, have self-fluxing properties when used on commercial coppers. Because of their alloying constituents, however, most copper *alloys* require the use of a flux, even when BCuP filler metals are employed. Lead-containing alloys require the protective action of flux to prevent formation of a dross that will seriously impair wetting and the flow of filler metal.

In some applications, however, the use of a flux is unacceptable because of special service requirements or because flux residues cannot be removed completely after brazing. In the example that follows, copper plating served to eliminate the need for flux in induction brazing cartridge brass to a leaded commercial bronze.

Example 653. Avoiding the Use of Flux by Copper Plating the Copper Alloy Components (Fig. 21)

The reversing-valve assembly for an air conditioner, shown in Fig. 21, required leakproof brazed joints between the body, made from alloy 260 (cartridge brass, 70%) tubing, and the cover, made from alloy 314 (leaded commercial bronze).

Two specific restrictions were imposed in brazing one of the cover joints (Fig. 21, section A-A): (*a*) during brazing, a nylon needle located ½ in. away from the brazed joint could not be heated above 450 F; and (*b*) it was essential that the joint be brazed without the use of flux — not only to minimize the possibility of leakage, but also because it was not possible to clean the inside of the joint after it was brazed.

By heating the joint in 15 seconds and quenching it with water as soon as the filler metal solidified, heat was sufficiently localized so that the nylon needle was not overheated. By plating both the end of the body and the cover with a 0.0002-in. thick-

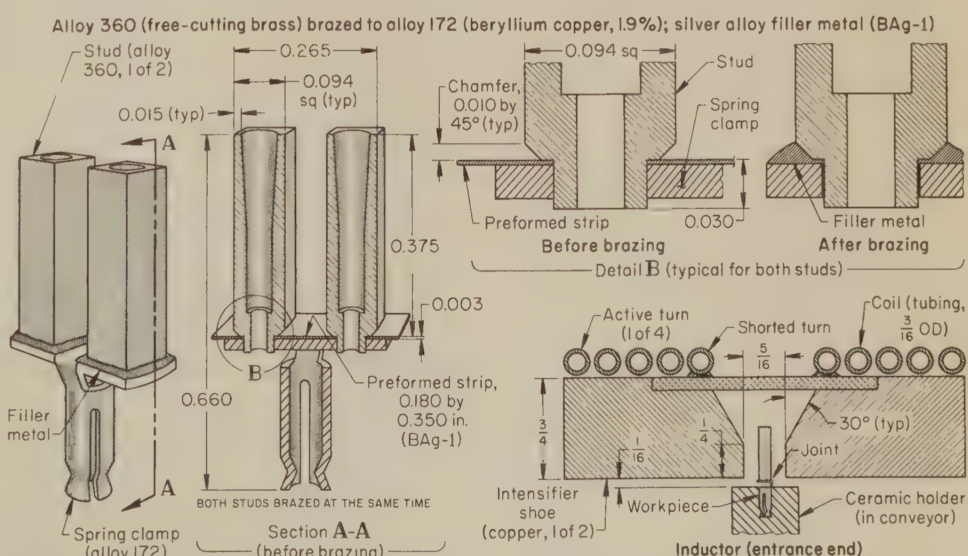

Fig. 19. Connector assembly and (at lower right) section through inductor used for conveyorized brazing (Example 651)

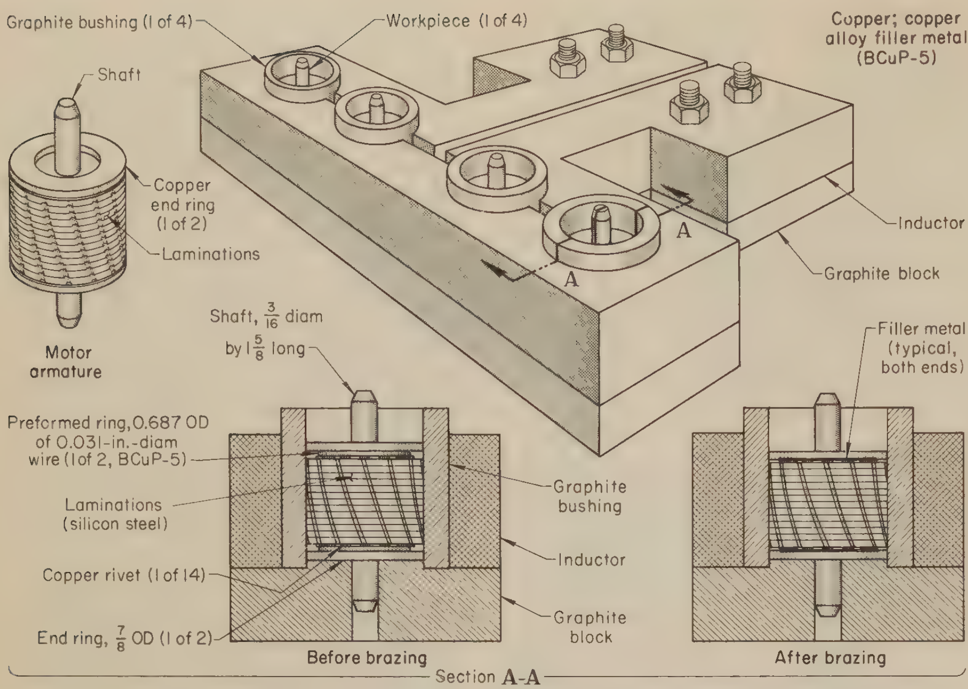

Fig. 20. Motor armature, and one of two four-station inductors used for high-production brazing of copper end rings to rivets holding armature laminations (Example 652)

ness of copper prior to brazing, leaktight joints were made without the use of flux.

The diametral clearance between the cover and the body was 0.002 to 0.010 in. When the two components were assembled, a preformed ring of BCuP-4 filler wire was pushed in place by hand, and then the end of the tube was crimped slightly, as shown in detail B in Fig. 21. Then the assembly was induction brazed, using a two-turn inductor (additional brazing conditions are given in the table with Fig. 21). Because of the short heating cycle (15 seconds), surfaces did not require postbraze cleaning and, following inspection, were immediately spray coated with black lacquer.

Joints were inspected 100% using a halogen-type leak detector that could detect leaks of the order of 10^{-5} standard cubic centimeters per second. The internal pressure at the time of testing was 400 psi. In addition, these assemblies were required to withstand 2600-psi internal pressure without rupture. The percentage of rejections due to leakage was extremely low (0.15%).

Cost of Brazing. The labor costs for induction brazing are usually lower than those for torch brazing, the process with which induction brazing is most often competitive. At high production rates, the total brazing cost per assembly generally favors induction brazing over torch brazing. However, the direct savings that accrue from the use of induction brazing will vary considerably among different plants because of differences in the time periods established for amortizing capital equipment. In the following example, the labor costs for brazing a bellows assembly by induction and by torch brazing are compared.

Example 654. Comparison of Labor Costs for Brazing a Bellows Assembly (Fig. 22)

Originally, torch brazing was used for joining the spring brass – gray iron bellows assembly shown in Fig. 22, at a production rate of 120 assemblies per hour. The chief advantage of torch brazing was low cost of equipment. Assemblies were prepared and brazed one at a time, requiring much skill and hand labor, at an hourly labor rate of \$3.60. Labor per assembly cost \$0.03.

To attain a higher production rate, induction brazing was substituted for torch brazing. The induction brazing setup consisted of two brazing fixtures, each of which accommodated four assemblies. Thus, one fixture was being loaded while the assemblies in the other fixture were being brazed. Less skill was needed to operate the induction brazing setup; hence the work could be done by personnel for whom the hourly rate was only \$2.16. At a production rate of 720 assemblies per hour (six times that of torch brazing), labor cost per assembly dropped to \$0.003.

Resistance Brazing

The chief use of resistance brazing is the joining of copper conductors, terminals and other parts in lap joints for electrical connections, where heating must be localized and closely controlled while brazing the joint, and the brazed joint must have low electrical resistance. Generation of heat in the filler metal and nearly complete filling with a thin layer of the filler metal in the joint help in meeting both of these objectives.

The filler metal most frequently used is BCuP-5, which in most applications is used without a flux when brazing copper. In spite of the comparatively low electrical conductivity of BCuP-5 (approximately 10% IACS, as shown in Table 1), there is no difficulty in producing brazed joints having a low voltage drop that is acceptable for nearly all applications, because the layer of filler metal in the brazed joint is very thin and because the joints are designed to provide a conducting contact region of larger area than the cross section of the smaller member.

Six examples of the production use of resistance brazing for making electrical connections on copper are presented in this article. The article on Resistance Brazing, pages 643 to 654, includes eight additional examples of resistance brazing of copper, and one (Example 602) in which the work metals were leaded brasses. Also included in that article are discussions of equipment, process applicability, electrodes, filler metals, fluxes, cleaning, joint design, and special techniques used.

Resistance brazing techniques described and illustrated by examples of practice in the remainder of the present article include brazing of multiple-strand copper wire, brazing of leads to commutator bars, brazing with portable machines and high-production resistance brazing.

Brazing of Multiple-Strand Copper Wire. Resistance brazing is the preferred brazing process for making connections of terminals or assemblies to stranded or braided copper electrical conductors. Torch brazing does not provide sufficiently localized or controlled heating for most applications of this type. Induction brazing, the only other brazing process that permits selective heating, provides well-controlled but somewhat less-localized heating than resistance brazing, and the equipment for induction brazing is more costly.

Resistance brazing, like other brazing processes, is often selected in preference to soldering, because of the higher strength of the filler metal.

The major arc welding processes usually are ruled out on the same basis as torch brazing; and arc processes that involve impact, such as stud and percussion welding, generally cannot be used because the stranded or braided copper conductors do not provide a rigid workpiece for the lap-type connections in common use (although T-joints of multiple-strand wires to flat surfaces have been made by percussion welding).

Resistance welding is not suitable for use on multiple-strand copper electrical conductors rated to carry a current higher than about 60 amp, because the amount of current needed to make the weld is prohibitively large. Such connections are made by resistance brazing using the "solidified joint" technique, as described in Examples 605 and 606.

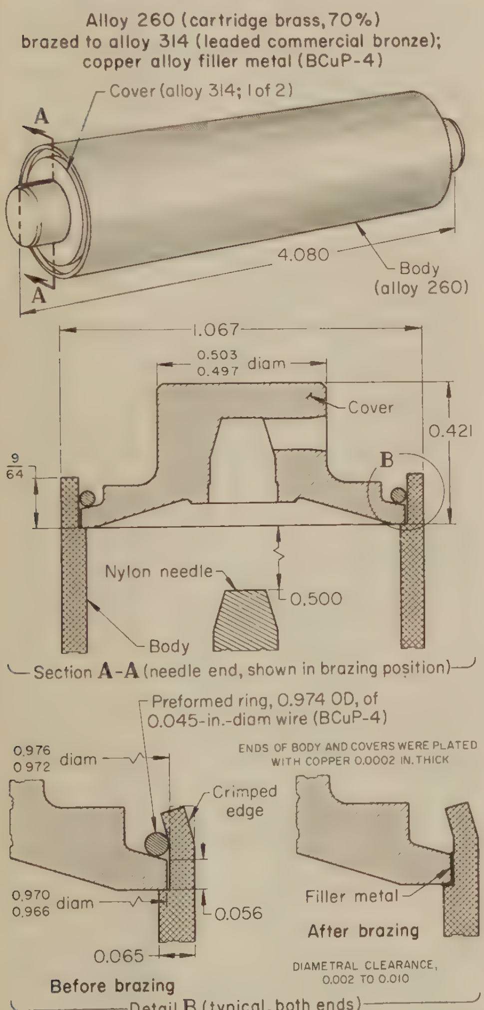
Connections to smaller multiple-strand conductors are made by either resistance welding or resistance brazing. Resistance welding has the advantage of requiring no filler metal, and is often faster than resistance brazing, as in Example 420. However, especially when the individual strands are small in diameter, it is difficult to prevent melting of strands in resistance welding. Resistance welding of a seven-strand silver-plated copper wire (strand diameter, 0.016 in.) to a coin silver (90 Ag, 10 Cu) ring in Example 422 depended on the beginning of melting at the silver-copper eutectic temperature (1436 F) and on carefully developed electrode design and operating conditions.

In the example that follows, resistance brazing was selected instead of resistance welding to join a 19-strand silver-plated copper wire (strand diameter, 0.014 in.) to a copper ring (instead of a silver alloy ring as in Example 422) in a similar arrangement, because the separate strands were melted by resistance welding of this smaller strand size.

The use of BCuP-5 filler metal in the resistance brazing procedure enabled melting to begin at a temperature of 1190 F and provided enough molten metal for effective heat transfer within the multiple-strand wire and from the wire to the copper ring, so that the strands did not overheat. The original joining procedure, based on manual tin-lead soldering, had been too slow and had produced joints of inconsistent quality, with excessive spreading of the solder.

Example 655. Use of Resistance Brazing in Preference to Soldering or to Resistance Welding, for Stranded Copper Wire (Fig. 23)

The electrical connection shown in Fig. 23 was originally made by manual soldering with a tin-lead alloy. Production rate was slow (about 60 connections per hour), the solder spread over an undesirably large

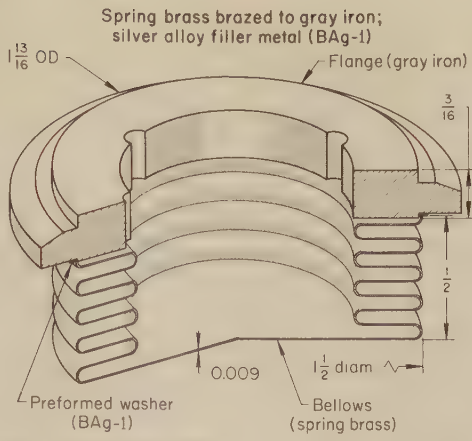


Conditions for Induction Brazing

Power supply	Vacuum-tube unit, 20 kw, 450 kHz
Inductor	Two-turn(a)
Fixture	For accurate centering and lengthwise positioning
Filler metal	BCuP-4, 0.045-in.-diam wire(b)
Flux	None
Heating time	15 seconds

(a) Made of 3/16-in.-OD copper tubing. Inside diameter of the inductor was 1 9/16 in. (b) Formed into a 0.974-in.-OD ring to fit the inside diameter of the body.

Fig. 21. Valve assembly that was induction brazed to avoid overheating the nylon needle, and selectively copper plated to avoid use of a flux (Example 653)



Item	Torch brazing(a)	Induction brazing(b)
Assemblies brazed per hour	120	720
Labor rate per hour	$3.60	$2.16
Labor cost per assembly	$0.03	$0.003

(a) The torch brazing data are based on a 30-second preparation and heating cycle, processing one assembly at a time. (b) In induction brazing, four assemblies were being brazed in a fixture while four additional assemblies were being loaded in a duplicate fixture.

Fig. 22. Compressor-seal bellows assembly joined at less cost by induction brazing than by torch brazing (Example 654)

area, and joint quality was unpredictable. Resistance welding was tried, but these attempts at directly fusing the 19-strand silver-plated copper wire to the copper ring failed because the temperature required to produce a bond invariably melted the thin (0.014-in.-diam) strands.

The method was changed to resistance brazing, using the setup illustrated in Fig. 23. The upper brazing electrode was made of RWMA class 14 material (molybdenum), and the lower electrode was made of RWMA class 2 material (chromium copper). As shown in the views at right in Fig. 23, the upper electrode had a 0.030-in.-deep groove with a 0.060-in. radius. This groove was wider than the wire and flattened it slightly when the electrodes closed. At the same time, the 0.030-in. depth was shallow enough to keep the electrode from touching the copper ring. The lower electrode was flat, so that it made line contact with the ring and concentrated the current flow and heating at the point of brazing.

The filler-metal preforms (wafers, 1/4 by 1/8 in., of 0.005-in.-thick BCuP-5) were manually placed at the bottom of the copper ring under the stranded wire.

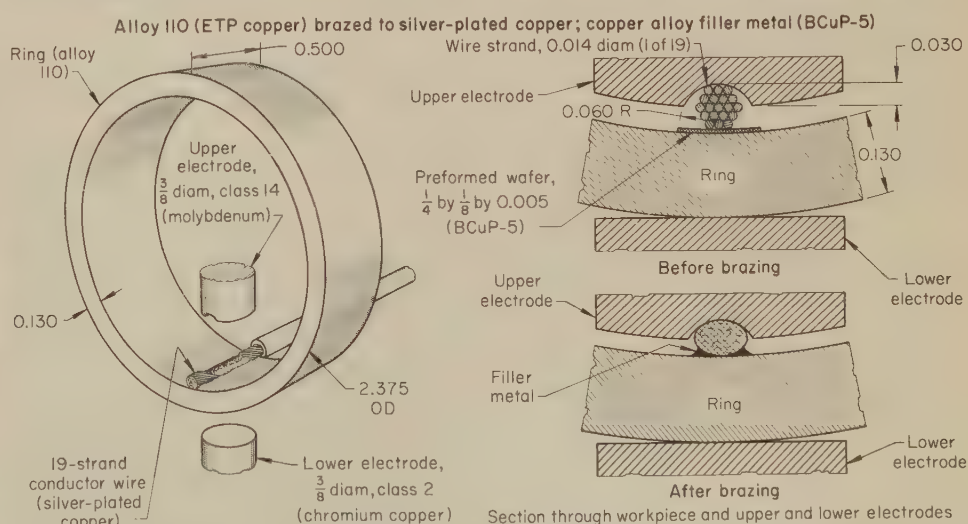
The ring (after degreasing) was placed on the bottom electrode with the filler metal directly above the contact point. A fiber support (not shown in Fig. 23) behind the electrode held the ring upright in brazing position. The end of the copper conductor wire was stripped of insulation and laid on the preform. No flux was used. The wire was hand held while the brazing cycle was initiated with a foot switch.

Additional brazing conditions are given in the table with Fig. 23.

Brazing of Leads to Commutator Bars. The suitability of resistance brazing for joining small copper electrical conductors to massive copper assemblies has led to the use of the process for attaching armature leads to commutator bars on large electrical motors and generators. Joints made by this method provide a large conducting cross section that prevents significant resistive heating at the connections in service. The joints are made at much lower temperature than would be possible by resistance welding, which could be done only with excessively high current and would also produce weaker joints and provide too small a conducting area at the joint.

The use of conventional resistance welding equipment and high-resistivity electrodes with specially contoured tips makes it possible to concentrate the heating at the joint, to keep the heating time to a minimum, and to obtain efficient handling and comparatively high production rates.

In the example that follows, resistance brazing replaced a slower and less



Conditions for Resistance Brazing

Conditions for Resistance Brazing

Machine	Press-type, air-operated 75-kva resistance welding machine	Filler metal	BCuP-5 preform, ¼ by ⅛ in., by 0.005 in. thick(a)
Electrodes	RWMA class 14 (molybdenum), water-cooled	Squeeze time	70 cycles
Electrode force	500 lb	Heating time	114 cycles(b)
Current	55 amp	Hold time	18 cycles
Voltage	1.5 v	Off time, minimum	120 cycles
		Brazing time, per joint	8 seconds

(a) Flux not used. (b) Six pulses, each of 11 cycles heating time plus 8 cycles cooling time.

Fig. 24. Assembly of armature leads to commutator bars, and setup for resistance brazing, which replaced staking and torch soldering, giving faster production and eliminating contamination and excessive annealing (Example 656)

satisfactory mechanical staking and torch soldering procedure that also produced unwanted heating effects.

Example 656. Resistance Brazing Instead of Torch Soldering for Lap-Joint Attachment of Armature Leads to Commutator Bars (Fig. 24)

The original method of making the commutator shown in Fig. 24 was to insert the alloy 110 armature leads into holes in the alloy 114 commutator bars, mechanically stake them, and finally solder with a tin-lead alloy. Joints were heated for soldering with a gas torch. Disadvantages of this method included slow production rate (30 seconds' soldering time per piece), contamination of working surfaces with solder and flux, and excessive annealing of the commutator bars under the slow heating with the torch.

The joint design was changed to the lap-type design shown in Fig. 24, in which flat copper armature leads were inserted in milled slots in the commutator bars and resistance brazed in place using BCuP-5 filler-metal preforms. With this filler metal no flux was required and, since filler metal did not bleed out of the joint, no postbraze cleaning was necessary. Before brazing, the leads were degreased in trichlorethylene. Because the slots were milled (without using a lubricant) just before brazing, no cleaning was necessary on the commutator bars.

Additional brazing conditions are given in the table with Fig. 24. By changing to the resistance brazing method, the time for making a connection was reduced by 73% (from 30 to 8 seconds).

In the next example, joint quality, localization and control of heat input, and initial cost of equipment were major factors in the selection of resistance brazing for attaching dual armature leads to commutator bars.

Example 657. Resistance Brazing Instead of Carbon-Arc Brazing for Joining Armature Leads to Commutators (Fig. 25)

When carbon-arc brazing was used for joining alloy 102 armature leads to alloy 110 commutator bars (see Fig. 25), the joints were porous and high in electrical resistance. This caused excessive temperature rise in the motors in which they were used.

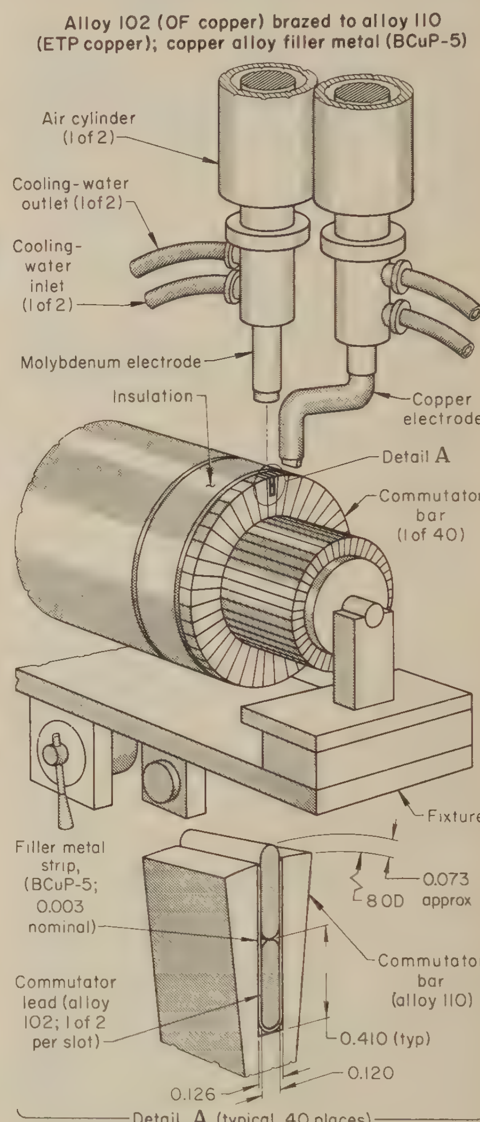
Changing the method of making the connections to resistance brazing, using BCuP-5 filler metal and the conditions listed with Fig. 25, eliminated the porosity and reduced the electrical resistance across the joint. A temperature of 1300 to 1350 F was required to ensure an acceptable joint. Torch brazing was ruled out because of excessive width of heating and inadequate heat control. Induction heating was rejected because the initial investment for equipment would have been too great.

The equipment included a 50-kva transformer with a 220-volt primary and taps on the secondary at 3.2, 3.8, 4.4 and 5.0 volts. As indicated in Fig. 25, the electrodes were air-operated and water-cooled.

The setup used for resistance brazing is shown in Fig. 25. The width of the slots in the riser portions of the commutator bars was increased by 0.006 in. to accommodate a U-shape strip of filler metal. Detail A in Fig. 25 shows the work arranged for brazing with the upper lead extending about 0.073 in. above the commutator bar, to be contacted by the molybdenum electrode. Neither fluxing nor prebraze cleaning was required.

To initiate the brazing sequence, a valve was manually actuated, and the air cylinders positioned and applied pressure to the electrodes. The contactor switch was then activated by a push button to energize the primary of the transformer. High secondary current heated the commutator bar in the area between the electrode tips (a red color was visible, starting at the tips and progressing to a point between them). The filler metal melted, the leads in the slot partially melted, and the leads were compressed approximately flush with the bar surface. Use of a controlled amount of filler metal made final grinding unnecessary.

Visual observation by the operator permitted him to terminate the heating sequence



Conditions for Resistance Brazing

Machine	Press-type, air-operated 50-kva resistance welding machine
Electrodes contacting commutator bar	RWMA class 1 (cadmium copper)
Electrodes contacting armature lead	RWMA class 14 (molybdenum)
Electrode force	80 lb(a)
Voltage	5.0 v(a)
Filler metal	BCuP-5, 0.003-in.-thick strip
Flux	None
Production per hour	Four commutators(b)

(a) Squeeze time, 10 sec; five heating pulses, each 2 sec long. (b) Forty-slot commutators.

Fig. 25. Arrangement for resistance brazing pairs of armature leads to commutator bars, to avoid porosity that was experienced when carbon-arc brazing was used (Example 657)

as soon as the leads in the commutator slot reseated themselves. The transformer circuit was then opened by a push button and cooling began. The electrodes were then retracted by releasing the air valve.

As a safety measure, a timer in the circuit limited brazing time to a maximum of 1 min. If required time exceeded this setting, the operator had to release and repush the operating button.

Brazing With Portable Machines. One common use of portable resistance welding machines for resistance brazing is attaching bus-bar terminals or similar strip-type connectors to large electrical equipment that cannot be brought to, or positioned for brazing in, a conventional fixed-position resistance welding machine.

Electrical connections to such equipment can often be made more economically by resistance brazing than by mechanical means, and are made more readily by resistance brazing than by arc welding.

In the example that follows, the selection of electrode material was important for successful results in resistance brazing strip-type copper bridging connectors to a large electrical apparatus, and cost was less than for making swaged or crimped connections using braided conductors.

Example 658. Use of a Portable Machine for Resistance Brazing of Strip-Type Connectors to Large Electrical Apparatus (Fig. 26)

The joints shown in Fig. 26 for the bridging connectors on electrical equipment were originally made using crimped swage connectors. Cost was high: $0.15 to $0.45 per joint, depending on the kva rating. Braided copper leads had to be used with this type of joint. On some equipment, connections were made at high cost by bolting.

The joint design was changed to that shown in Fig. 26, using strip-type connectors 0.040 in. thick by 1 in. wide. (Similar joints, not shown in Fig. 26, were also made in the same way using connectors 0.080 in. thick by 2 in. wide.) With the revised joint design, gas tungsten-arc welding was tried, but it was impossible to produce fusion over a sufficiently large area to provide adequate current-carrying capacity across the joint.

The next attempt, using the revised joint design, was resistance brazing using carbon electrodes, but excessive heat was generated at each brazed joint, with the extent of overheating depending on the condition of the carbon electrodes. Molybdenum-faced electrodes were substituted, and joints resistance brazed using BCuP-5 filler metal were made economically and with minimum damage to the electrical insulation near the joint.

Production rate and unit labor cost were approximately the same as for the mechanical joint, but the cost per joint of $0.005 for filler metal resulted in a substantial saving, as compared to the original material cost of $0.15 to $0.45 for a swage connector. Rejection rate for joints made by the resistance brazing method was less than 0.5%, and defects were repairable.

Additional data on equipment, operating conditions and results are given in the table accompanying Fig. 26.

Resistance brazing done with portable resistance welding machines is a convenient and economical way of interconnecting large copper electrical bus bars or of attaching either large or small copper bus bars to motor-generators, transformers and other electrical equipment. Lap joints made in this way have a bonding area that provides adequate strength and current-carrying capacity. Joints that have a large area of contact are brazed by making a series of spot brazes that overlap to provide full-joint or nearly full-joint bonding.

The low melting temperature of the filler metal helps to avoid overheating and excessive annealing of the work, and the usual selection of self-fluxing BCuP-5 alloy for the filler metal avoids corrosion problems and the need for flux removal.

In the example that follows, production time was cut in half and waste of filler metal was eliminated by changing from torch brazing to portable-machine, multiple-spot resistance brazing, for making a bus-bar connection of large area.

Example 659. Resistance Brazing Instead of Torch Brazing for a 32-Sq-In. Lap Joint on Bus Bar (Fig. 27)

The bus bar and strip assembly shown in Fig. 27 served as a terminal for a transformer. Originally the two alloy 110 components were joined by torch brazing using a filler metal of the BAg series. Torch brazing required the operator to use both hands — one to hold the torch and the other to feed the filler metal. Consequently, it was necessary to clamp the assemblies for brazing. In addition, some of the silver alloy filler metal was wasted by dropping on the floor.

By the improved method, the components were joined by multiple-spot resistance brazing in a portable resistance welding machine, using a 4-by-8-in. preformed strip of 0.005-in.-thick BCuP-5 filler metal between the bus bar and strip, as shown in Fig. 27. This method reduced production time by 50%, and eliminated waste of filler metal and the need for clamping.

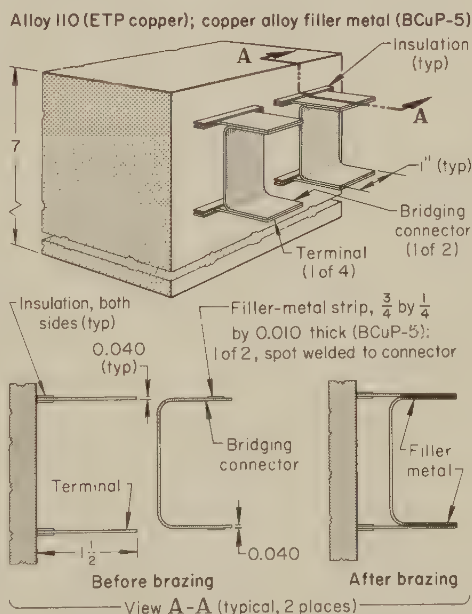
The material being joined was received in good condition and no precleaning was necessary. Also, since no flux was required with BCuP-5, no cleaning after brazing was needed. Brazing was done with a 22-kva machine equipped with manually operated water-cooled tongs having carbon-graphite electrodes. The area of each electrode face was approximately 1 sq in. Current was controlled by the operator with a foot switch. Maximum current flow was 2000 amp.

The filler metal was melted at each braze spot in an area larger than that of the electrode, providing bonding on 80% or more of the total joint area.

The same general technique was used for resistance brazing similar transformer terminals consisting of components smaller than those shown in Fig. 27.

In making the smallest connections of this type, in which ½-in. by 0.012-in. by 2½-in.-long copper bus bar was joined to copper strip 1¾ in. wide by 0.010 in. thick, ⅜-in.-diam copper-coated carbon-graphite electrodes were used with tongs that were not water-cooled. Thus, joint area was from 32 sq in. for the largest size to 0.88 sq in. for the smallest size.

High-Production Resistance Brazing. Production rates approaching those obtained in mass-production resistance welding are achieved in resistance brazing of some high-volume small copper parts, in spite of the need for an added operation to place filler metal (and, sometimes, flux) in the joint (see the section "Resistance Brazing as a High-Production Process" on page 650 in the article on Resist-

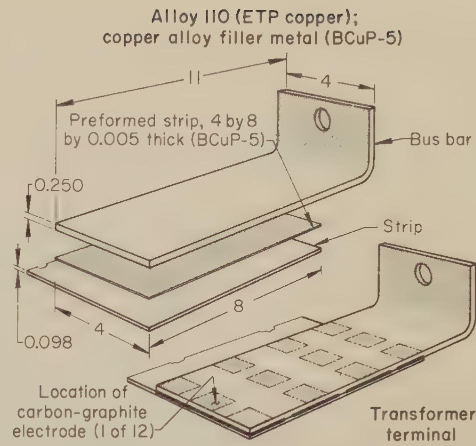


Conditions for Resistance Brazing

Machine	Portable resistance welding machine with internal cooling system
Electrodes	RWMA class 1 (cadmium copper), with RWMA class 14 (molybdenum) facing
Filler metal	BCuP-5, preformed strip, ¾ by ¼ in., by 0.010 in. thick
Flux	None
Production per hour	15 two-joint assemblies
Annual production	50,000 assemblies
Rejection rate	Less than 0.5%
Filler-metal cost per joint	$0.005
Savings per joint(a)	$0.145 to $0.445

(a) Compared with cost of swage connector used in original mechanical joining method

Fig. 26. Joints of strip-type bridging connectors to large electric apparatus made by resistance brazing, using a portable machine, at lower cost than original mechanical joints of braided connectors (Example 658)



Conditions for Resistance Brazing

Fixtures	None
Electrodes	Carbon-graphite, 1 in. square
Electrode force	Hand pressure by operator
Filler metal	BCuP-5 strip (see drawing)
Flux	None
Brazing current	2000 amp (max)
Heating time	Controlled manually by observation of filler-metal flow
Joint area	32 sq in.
Number of braze spots	12(a)

(a) The filler metal was melted at each braze spot in an area larger than the electrode area, thus providing bonding on 80% or more of the total joint area.

Fig. 27. Transformer terminal that was assembled by manual multiple-spot resistance brazing using carbon-graphite electrodes, instead of the original torch brazing procedure (Example 659)

ance Brazing). When resistance brazing copper parts in large quantities, the self-fluxing filler metal BCuP-5 is usually selected, so that there is no need to add flux before brazing and to remove flux residues afterward.

In some applications, filler metal for resistance brazing can be provided in the form of a suitable coating already present on one or both members to be joined, thus eliminating not only the use of flux but also the operation of placing filler metal at the joint. This was done in Example 603, in which copper wire was joined by high-speed resistance brazing to copper terminals clad with BCuP-5 filler metal.

In the example that follows, a critical feature was complete removal of oxide from a high-carbon steel spring before electroplating it with copper and silver. The plating served as filler metal for resistance brazing a braided copper wire to the steel spring.

Example 660. Mass-Production Resistance Brazing of Braided Copper Wire to a High-Carbon Steel Spring Electroplated With Copper and Silver (Fig. 28)

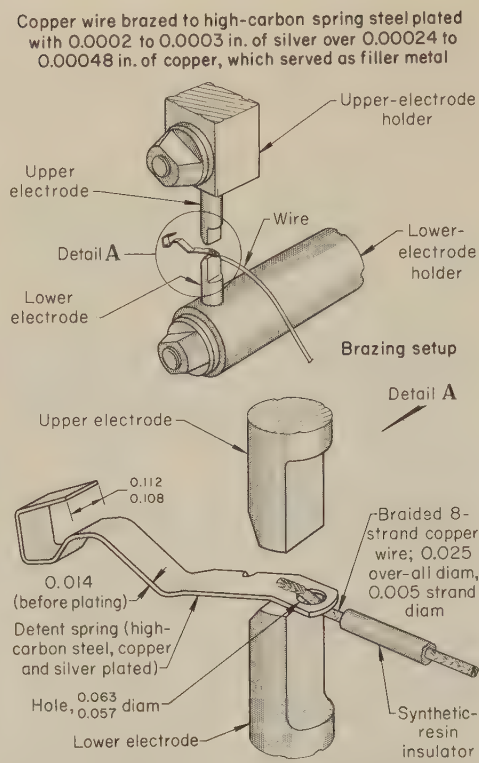
The detent-spring assembly shown in Fig. 28 was resistance brazed in mass production with the aid of plated-on filler metal on the steel spring (a copper plate 0.00024 to 0.00048 in. thick and an overlay of silver plate 0.0002 to 0.0003 in. thick). When heat was applied, a relatively low-melting copper-silver alloy was formed that provided sufficient filler metal to permit joining the stranded copper wire to the steel spring without significant fusion of the base metals. This assembly was resistance brazed at a production rate of 927 pieces per hour for use in an electric shaver.

Rejection rate at first was excessive in resistance brazing this assembly, because of frequent failure of the wire to adhere to the spring after brazing. In many instances, broken strands of wire exceeded the permissible 10% of the total strands. An examination of the resistance welding machine showed that it was functioning properly and that settings and electrode materials were correct for the production of sound joints.

The copper conductor wire was 0.025 in. in over-all diameter and of stranded construction. The spring was 0.014-in.-thick high-carbon steel (0.70 to 0.80% C) with silver plating over a copper underplate, as described above. Examination of the spring showed that a heavy oxide layer was present on the steel surface underneath the plating. When the oxide coating was removed before electroplating, the wire and spring could be brazed together satisfactorily. Proper control of the protective atmosphere while hardening and tempering the spring to Rockwell C 45 to 49 prevented the formation of the interfering oxide layer.

At the same time, it was determined in tests that braided wire suffered fewer broken strands during brazing than did stranded wire. Therefore, a change was made to 8-strand braided wire with 20 to 30 picks per inch. This wire had an over-all diameter (excluding insulation) of 0.025 in. and a strand diameter of 0.005 in.

After these changes were made, acceptable joints were produced with high reliability at an over-all production rate of 927 joints per hour. Joints had to withstand a force of 1 lb in a pull test. Frequency of sampling for the pull test was two assemblies from each 75. Additional brazing conditions are given in the table with Fig. 28.



Conditions for Resistance Brazing

Machine	Semiautomatic, air-operated resistance welding machine

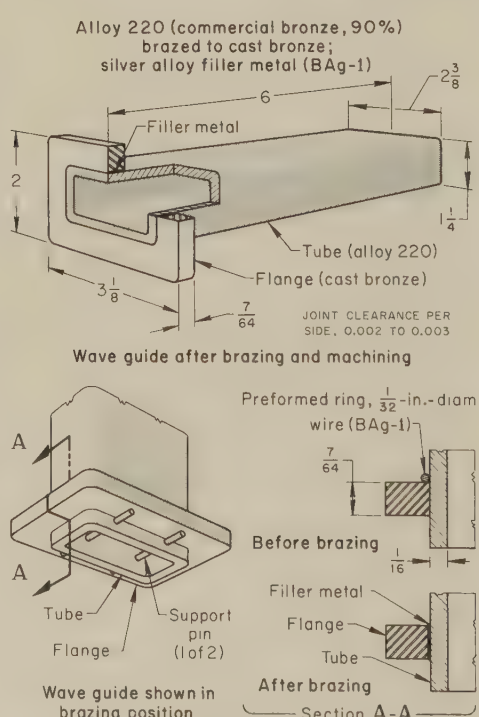

Fig. 29. Wave-guide assembly that was brazed by partial immersion in a molten salt bath (Example 661)

Dip Brazing

Salt bath furnaces used for the silver brazing of steel assemblies can be used also for silver brazing of copper and copper alloys. The same neutral salts, operating temperatures, and brazing procedures are used for dip brazing of most copper alloys as are used for steel (see the article on Dip Brazing of Steel in Molten Salt, which begins on page 655 in this volume).

Typical applications of dip brazing of copper alloys in molten salt are: wave guides and wave-guide hardware, flowmeter hardware, and capillary-tube-and-bellows assemblies.

The support given immersed workpieces by the buoyancy of the molten salt, and the rapid and even heating afforded by dip brazing, make this process especially suitable for joining assemblies that require minimum distortion, such as wave guides. When a wave-guide assembly has a large number of brazed joints, some external and some internal, a salt bath is particularly efficient for simultaneous brazing of all joints in a single immersion in the molten salt. With dip brazing, a flange fitting and the end of a wave-guide tube to be joined to it can be brazed by immersing only the joint portion in the molten salt bath, as in the example that follows.

Example 661. Use of Dip Brazing To Minimize Distortion (Fig. 29)

The wave-guide assembly shown in Fig. 29, which consisted of a straight tube of alloy 220 (commercial bronze, 90%) and a flange of cast bronze, was used in electronic equipment. It was required that the dimensions of the thin-wall tube (1¼ by 2⅜ in., by 1/16-in. wall) be maintained to close tolerances, and dip brazing was chosen as the joining process in order to avoid unacceptable amounts of warpage. (Torch brazing had been tried but resulted in excessive distortion.)

After any burrs were removed from the joint area, the tube and flange were degreased, bright dipped, rinsed in water, and dried. The parts were assembled so that the tube extended through the flange. Two accurately located sets of holes were drilled through the longer sides of the rectangular tube, and a pin was inserted through each set of holes to support the flange in the vertical position during brazing.

Filler metal in the form of a rectangular preform of 1/32-in.-diam BAg-1 wire was placed around the tube and adjacent to the flange (opposite the face). Type 3A flux was applied to the joint area, and the assembly was preheated in an oven to 600 F for 5 min to dry the flux and shorten the time required in the brazing bath.

For brazing, the assembly was supported vertically (flange down) on a rack, which was suspended from a rod extending through the tube. Supported in this manner, the assembly was self-jigged with gravity locating of the flange. (Self-jigging by staking was used on some similar wave-guide assemblies, and tack welding was used on others.)

Several assemblies simultaneously were partly immersed to a depth of about 3 in. for 1¼ min in a molten bath of neutral chloride salt (55% barium chloride, 25% sodium chloride, 20% potassium chloride) operated at 1350 F. After brazing, the assemblies were allowed to cool in air to approximately 500 to 600 F before they were washed in hot water to remove any residue of salt and flux, rinsed in hot water, bright dipped to remove slight oxidation that formed during cooling, rinsed in cold water, and dried.

Uniform fillets were formed and satisfactory joint penetration was obtained. The flange face was subsequently machined, which also removed a portion of the tube that extended beyond the flange. The final dimensions of the assembly were within tolerance.

Temperature Conversions

The general arrangement of this table was devised by Sauveur and Boylston more than 40 years ago. The middle columns of figures (in **boldface** type) contain the readings (°F or °C) to be converted. If converting from degrees Fahrenheit to degrees Centigrade, read the Centigrade equivalent in the column headed "C". If converting from Centigrade to Fahrenheit, read the Fahrenheit equivalent in the column headed "F".
